

Shifting, Not Lifting: Minimum Wages and Low-Skilled Workers in Peru*

Eric Torres Ramírez

This version: July 5, 2026

Abstract

Whether a minimum wage helps the workers it targets depends on how many of them it reaches—and on whether anyone complies with it. I study Peru’s May 2022 increase in the national minimum wage, from 930 to 1,025 soles. Peru sets a single national floor, so identification comes from differential exposure: on the eve of the reform a majority of low-education wage earners were paid below the new minimum, against two fifths of the high-education comparison group. Using quarterly ENAHO data (2021–2024), I find that the reform did not lift the pay of the workers it targeted, even though the floor was honored where enforcement reaches: within the formal sector the earnings spike at the old minimum migrates almost completely to the new one, but formal jobs account for only 13 percent of low-education employment, informal pay drifted further below the floor, and relative wages did not rise. What moved was the composition of employment: formal employment of low-education workers fell by 4.6 percentage points—a fifth of its baseline—and self-employment rose by 3.6 points, with flat pre-reform trends, larger shifts in high-bite departments, and confirmation from a continuous regional-exposure design under randomization inference. An identically sized increase in January 2025, in a calmer labor market, produced no comparable reallocation. Where informality is pervasive and enforcement weak, minimum wage increases shift low-skilled workers across employment arrangements more than they raise their pay, qualifying the “lighthouse” view of the Peruvian minimum wage found for earlier reforms.

Keywords: minimum wage; informality; education; difference-in-differences; Peru.

JEL codes: J23, J31, J38, J46, O17.

*This paper uses the public-use quarterly employment modules of the Encuesta Nacional de Hogares (ENAHO) of the Instituto Nacional de Estadística e Informática (INEI). All estimates use survey weights; the replication package is available in the accompanying repository. All errors are the author’s own.

1 Introduction

Whether a minimum wage helps the workers it targets depends on how many of them it actually reaches. In developing countries a large share of employment lies outside the reach of labor regulation, so a statutory wage floor can raise pay for covered workers, displace some of them into the uncovered informal sector, or act only as a reference point for wages that formal firms would have paid in any case. Which of these forces dominates is an empirical question, and its answer turns on how binding the floor is, how well it is enforced, and how freely workers move between the formal and informal margins. I study these questions for Peru, a country that pairs a minimum wage high relative to median pay with one of the highest rates of labor informality in Latin America.

I exploit the increase in Peru’s national minimum wage (the *Remuneración Mínima Vital*, or RMV) from 930 to 1,025 soles, enacted by Supreme Decree 003-2022-TR and effective on 1 May 2022. This 10.2 percent nominal increase was the first change to the RMV in four years, and it occurred as the labor market was emerging from the pandemic. A central institutional fact shapes the analysis: Peru sets a single national minimum wage, with no regional or sectoral variation in the general regime. There is therefore no cross-sectional variation in the level of the policy and no staggered adoption to exploit. As Jiménez (2023) notes for the 2016 reform, credible identification must instead come from differential *exposure* to a policy that changes for everyone at the same time.

My source of differential exposure is education. In the pre-reform quarters the median monthly-equivalent wage of a low-education private wage earner was 950 soles, almost exactly the old minimum of 930, and 57 percent of low-education wage earners were paid below the *new* floor of 1,025 soles on the eve of the reform; a ten percent increase in that floor is therefore highly binding for this group. High-education workers, by contrast, have a median wage well above the minimum and are less likely to be bound by it, although a substantial minority remains exposed through informal or own-account work. This gap in exposure, rather than a claim of zero exposure for the comparison group, motivates a difference-in-differences design that contrasts low-education workers (those with at most complete secondary schooling, about two thirds of the working-age population) with high-education workers (those with any tertiary schooling). The design applies a long tradition of measuring minimum wage effects from variation in the “bite” of the policy across groups or regions (Card, 1992; Lee, 1999; Machin et al., 2003) to a setting with a single national reform and rich, quarterly household data.

I use the public-use quarterly employment modules of the Encuesta Nacional de Hogares (ENAH) from 2021Q1 through 2024Q4, which bracket the reform with five pre-reform and

ten clean post-reform quarters; the transition quarter 2022Q2, in which the reform took effect mid-quarter, is excluded from the baseline and restored in a robustness check. The data are repeated cross-sections, and their quarterly frequency lets me estimate a dynamic event study, test for differential pre-trends by education, and trace the effect for more than two years after the reform. I examine a broad set of outcomes: real hourly wages and monthly earnings, the probability of employment and of labor force participation, the incidence of formal versus informal employment, hours of work, and the split of employment between wage work and self-employment. Throughout I weight by the survey weights and cluster inference by department, and because treatment is assigned at a coarse level I complement conventional cluster-robust standard errors with the small-sample correction of Pustejovsky and Tipton (2018) and with randomization inference.

Three findings emerge. First, and most robustly, the reform shifted the *composition* of low-education employment away from formal wage work. The probability that a low-education worker holds formal employment falls by 4.6 percentage points—about a fifth of the group’s 23 percent baseline formality rate—and self-employment rises by 3.6 points. These estimates have statistically flat pre-reform trends (for formality), appear immediately after the reform and persist, are larger in the departments where the new floor cuts deeper into the wage distribution, and are confirmed by an independent continuous-exposure design that relates outcomes to the pre-reform regional Kaitz index and supports design-based randomization inference. Second, there is no evidence that the reform lifted the group’s pay—but not because the floor is a dead letter. Within the formal sector, where enforcement operates, the earnings spike at the old minimum migrates almost completely to the new one, and the share of formal wage earners paid below the new floor falls; among informal wage earners that share *rises*, and because only 13 percent of employed low-education workers are formal, the two responses cancel: the aggregate below-floor share does not move, no decile of the wage distribution shows a gain, and the estimated effect on the average log real hourly wage is negative and insignificant. The no-lift conclusion rests on the compliance and distributional evidence, whose diagnostics are clean; the average wage regression itself carries a rejected pre-trend test, driven by a single early-2021 quarter, and I bound rather than oversell what it can rule out. Third, the employment rate of low-education workers falls by 2.5 percentage points, but this margin is the least robust: it fails in-time placebo tests, has a clear differential pandemic-recovery pre-trend, and does not scale with regional exposure, so I do not give it a causal interpretation. Throughout I bound conclusions with the sensitivity analysis of Rambachan and Roth (2023) and a battery of specification and placebo checks. I then replicate the whole design on the January 2025 reform, which raised the RMV to 1,130 soles in a calmer, post-pandemic window: no wage response appears there

either, and neither does the reallocation, which I interpret as evidence that the margin along which the minimum wage binds depends on the state of the labor market.

The contribution is a combination rather than a new tool, and I state it without overclaiming. To my knowledge this is the first evaluation of the 2022 Peruvian minimum wage reform and the first study of any Peruvian reform using the post-pandemic quarterly ENAHO; the existing micro evidence stops at the 2016 reform (Jiménez, 2023) or at the reforms of the early 2000s (Jaramillo and López, 2006; Céspedes, 2005). It is also the first to make heterogeneity by education the central object of a worker-level event study of the Peruvian minimum wage, where prior work cuts heterogeneity by income range or age or constructs a department-level dose of exposure. And it places the informal margin at the center of the analysis, showing that adjustment runs through the composition of employment rather than through pay. I claim no novelty for the identification idea, which is the standard exposure or bite design, nor for the econometric toolkit; the value added is the pairing of a new reform and a policy-relevant post-pandemic period with an education-based worker-level design and a careful treatment of informality and of the threats to identification that such a design entails.

The rest of the paper proceeds as follows. Section 2 describes the Peruvian minimum wage and the reform, and Section 3 places the paper in the literature. Section 4 presents the data and the construction of the key variables, and Section 5 sets out the empirical strategy and the identifying assumptions. Section 6 reports the main results, Section 7 the robustness and inference checks, and Section 8 the heterogeneity and distributional analysis. Section 9 discusses mechanisms, external validity, and limitations, and Section 10 concludes.

2 Institutional background

2.1 The Peruvian minimum wage

Peru sets a single national minimum wage, the *Remuneración Mínima Vital* (RMV), which applies to workers in the private-sector labor regime. Unlike federal systems such as the United States or Brazil, and unlike countries with occupational or regional wage floors, Peru has no sub-national or industry-specific statutory minimum in the general regime. A small number of special regimes are indexed to the RMV—mining carries a statutory premium over it, the agrarian regime of Ley 31110 sets a daily remuneration anchored to it, and the small-enterprise (MYPE) regime applies the same floor—so none introduces

cross-sectional variation in the level of the policy.¹ The consequence for research design is decisive: because the level of the RMV is common to the whole country, there is no cross-sectional variation in the policy and no staggered timing of adoption. Any credible research design must therefore exploit differences in how exposed workers are to a change that reaches everyone simultaneously.

In principle the RMV is to be adjusted periodically by the tripartite National Labor Council in line with inflation and productivity. In practice the Council has never set the RMV, and the level is fixed at the discretion of the executive through a Supreme Decree. Adjustments are consequently infrequent and irregular in both timing and magnitude, and Peru is among the most volatile minimum wage setters in the region (Jiménez, 2023; Céspedes, 2005). The RMV had stood at 930 soles since April 2018.²

Two features make the RMV unusually binding by international standards. First, its ratio to the median wage is high. In my pre-reform sample the national median monthly-equivalent wage of a private wage earner is 1,000 soles, so the old minimum of 930 stood at 93 percent of the median, the new minimum slightly above it, and the Kaitz index, the ratio of the minimum to the median wage, is close to one nationally and approaches two in the poorest departments. Second, compliance is far from universal. Consistent with earlier work (Jaramillo and López, 2006; Céspedes, 2005), a large share of workers earn below the statutory floor, especially in rural areas, in small firms, and in the informal sector, while compliance inside registered formal firms is high. Enforcement capacity is limited.³ These features imply that a nominal increase in the RMV can bind mechanically for formal workers near the floor while leaving much of the informal sector formally uncovered, so that the policy’s real reach depends on the degree of informality and on the ease of movement across the formal and informal margins.

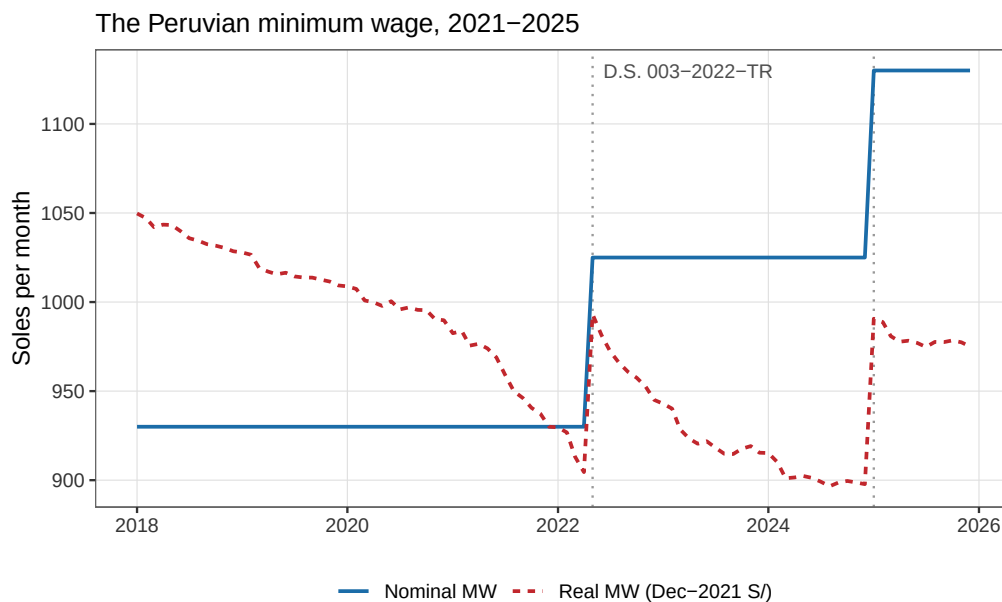

2.2 The 2022 reform

The reform I study was enacted by Supreme Decree 003-2022-TR, published on 3 April 2022, and took effect on 1 May 2022. It raised the RMV from 930 to 1,025 soles, an increase of

¹Because the agrarian regime pays a daily remuneration under separate rules, I flag agriculture throughout and show robustness to excluding it (Section 7).

²Fixed by Supreme Decree 004-2018-TR. The two preceding increases raised the RMV from 750 to 850 soles in May 2016 and from 850 to 930 soles in April 2018, so the 2022 reform followed an unusually long freeze.

³Labor inspection is the responsibility of the National Superintendency of Labor Inspection (SUNAFIL), whose inspection staff is thin outside Lima. Earlier work estimates overall non-compliance with the RMV at roughly 30 to 40 percent, concentrated in rural areas, small firms, and the informal sector (Jaramillo and López, 2006; Céspedes, 2005).

Vertical lines: reforms effective 1 May 2022 and 1 Jan 2025. Real series deflated by Lima CPI (Dec-2021=100).

Figure 1: The nominal and real Peruvian minimum wage, 2021–2025. The real series is deflated by the Lima consumer price index (December 2021 = 100). Vertical dotted lines mark the reforms effective 1 May 2022 (Supreme Decree 003-2022-TR) and 1 January 2025 (Supreme Decree 006-2024-TR).

95 soles or 10.2 percent, the first change in four years. Figure 1 plots the nominal and real value of the RMV over 2021–2025. Two points are worth noting. The nominal increase of 10.2 percent was partly offset by inflation, which ran at roughly 8 percent over 2022, so the increase in the real value of the floor was more modest and eroded over the following two years. This tempers the expected size of any wage response and is relevant when comparing my estimates with those from lower-inflation episodes. The reform also occurred during the post-pandemic recovery, a period of unusual labor market turbulence that I address explicitly in the empirical analysis.

A second reform, enacted by Supreme Decree 006-2024-TR and effective on 1 January 2025, raised the RMV further to 1,130 soles. This change falls just outside my main study window, but the ENAHO quarters for 2025 are available and I use this second reform as an out-of-sample replication of the design in Section 7. The two reforms are of very similar magnitude, 10.2 percent each, which makes the 2025 episode a natural validation exercise in a calmer, post-pandemic environment.

3 Related literature

My paper connects three strands of research: the theory and evidence on minimum wage employment effects, the evidence for developing countries with large informal sectors, and the specific literature on Peru.

Theory and the canonical evidence. The competitive model predicts that a binding wage floor reduces employment among low-productivity workers, with an effect whose size depends on labor demand elasticities and on the fraction of workers bound by the floor (Brown, 1999). Models with employer wage-setting power deliver different predictions: under monopsony a moderate minimum wage can raise employment, and it typically compresses the lower tail of the wage distribution (Manning, 2003). The empirical literature has moved from a presumption of sizable disemployment toward a consensus of small effects on the margin studied. The case study of Card and Krueger (1994) and the broader synthesis in Card and Krueger (1995) found little evidence of job loss from the New Jersey reform, and the border-discontinuity design of Dube et al. (2010) and the bunching approach of Cengiz et al. (2019) likewise find that recent United States increases raised wages at the bottom with limited employment effects; Manning (2021) reads the accumulated evidence as an “elusive” employment effect, while Neumark and Wascher (2007) offer the skeptical reading. Harasztosi and Lindner (2019) show that a large Hungarian increase was absorbed mostly through prices rather than employment. Closest to my mechanism, Dustmann et al. (2022) show that the German minimum wage operated through *reallocation*—moving workers across establishments—rather than through employment losses, and Engbom and Moser (2022) document how a rising Brazilian minimum compressed the formal wage distribution; Derenoncourt and Montialoux (2021) trace distributional consequences of coverage extensions in the United States. A recurring theme, which I build on directly, is that effects should be measured where the minimum “bites.” Card (1992) uses regional variation in the fraction of workers affected, Clemens and Wither (2019) follow workers whose wages sat below a rising federal floor, Lee (1999) uses the gap between the minimum and the median wage, and Machin et al. (2003) exploit a low-wage sector in which the introduction of the United Kingdom minimum was especially binding. My education-based design is an application of the same logic to a single national reform.

Developing countries and informality. In economies with large informal sectors the minimum wage interacts with the boundary between covered and uncovered work, and two opposing forces appear repeatedly. A “lighthouse” effect can raise wages even in the in-

formal sector, where the minimum serves as a norm or reference (Lemos, 2009; Bosch and Manacorda, 2010; Maloney and Núñez Méndez, 2004), while a reallocation effect can push workers out of formal employment and into informal or self-employed arrangements (Ham, 2018); Ulyssea (2018) provides the modern equilibrium framework in which regulation shifts firms and workers across the formality boundary. The Latin American evidence spans this range. Early work on Mexico and Colombia found disemployment where the floor was high relative to wages (Bell, 1997), and Gindling and Terrell (2007) show for Costa Rica that legal floors move wages only in the covered sector. Studies of Brazil find wage compression with small employment effects and evidence of spillovers into the informal sector (Lemos, 2009, 2004); Jales (2018) estimates, with a density approach, that the Brazilian minimum moves a substantial share of workers into informality. Work on Ecuador finds positive wage effects concentrated among low-income workers (Wong, 2019), and Arango et al. (2022) collect the recent Colombian evidence. The Honduran case is the clearest counterexample to the lighthouse view: Ham (2018) documents that a high minimum wage reduced covered employment and shifted workers toward informality, with no reduction in poverty. For Uruguay, Katzkowicz et al. (2021) use a density-discontinuity approach in the domestic-work sector to show that effects concentrate among the least skilled. The common methodological thread is the use of exposure or bite measures, either geographic Kaitz indices or fraction-affected shares, and a careful accounting of the informal margin, both of which I adopt.

Peru. The domestic literature is thin and, until recently, dated; the margin I emphasize has, however, begun to attract attention, with Corcuera (2024) studying the response of informal self-employment to Peruvian minimum wage increases in earlier data. Early studies of the reforms of the early 2000s find small and often statistically weak effects. Jaramillo and López (2006) analyze the 2003 increase using short quarterly panels for metropolitan Lima and conclude that the reform was largely innocuous, with negative employment-retention effects concentrated near the floor and evidence of displacement from the formal to the informal sector. Céspedes (2005) estimates a weakly significant employment elasticity of about -0.13 and shows that the RMV Granger-causes formal wages, an early statement of the lighthouse view for Peru. The most credible modern study is Jiménez (2023), who evaluates the 2016 reform using a difference-in-differences design with a department-level treatment dose, defined as the pre-reform share of formal workers earning between the old and new minimum. That study finds no disemployment, a rise in formality of 2.5 to 2.8 percentage points, and wage gains of 4.1 to 5.4 percent, and it interprets the pattern through employer market power, of the kind Amodio and de Roux (2021) document directly in Colombian manufacturing plants. My paper differs from this precedent in three respects that I make

explicit. I study a later reform and the post-pandemic period; I define exposure at the worker level through education rather than at the department level; and I find a different pattern of adjustment, with no wage gain and a decline rather than an increase in formality. I return to the reconciliation of these findings in Section 9. As Jiménez (2023) emphasizes, the binding constraint for any Peruvian design is the absence of sub-national variation in the nominal minimum, which forces the researcher to manufacture differential exposure; my contribution is to do so through the education dimension and to trace the consequences for the formal and informal margins.

Econometrics of difference-in-differences. Methodologically I rely on the modern difference-in-differences literature. Because my reform occurs at a single date, the recent concerns about negative weighting and forbidden comparisons under staggered adoption (Goodman-Bacon, 2021; de Chaisemartin and D’Haultfuille, 2020; Sun and Abraham, 2021; Callaway and Sant’Anna, 2021) do not bind: with a common treatment date the two-way fixed-effects estimator and its event-study analog are unbiased for a convex average of group-time effects (Roth et al., 2023; Baker et al., 2022). I nonetheless use the doubly robust estimator of Sant’Anna and Zhao (2020) as a building block, and I take the threat to identification, namely differential trends by skill, seriously through the sensitivity analysis of Rambachan and Roth (2023). For inference with few clusters I follow Bertrand et al. (2004), Cameron et al. (2008), and Pustejovsky and Tipton (2018); selection into the wage sample is bounded with the trimming approach of Lee (2009). Distributional effects are estimated with the unconditional quantile method of Firpo et al. (2009).

4 Data and measurement

4.1 The ENAHO quarterly employment modules

I use the public-use quarterly files of the Encuesta Nacional de Hogares (ENAHO), the national household survey conducted by Peru’s Instituto Nacional de Estadística e Informática (INEI). ENAHO is a nationally representative, stratified, multi-stage survey with continuous fieldwork; the quarterly employment and income module (module 500) records detailed labor market information for each household member of working age. I pool the sixteen quarters from the first quarter of 2021 through the fourth quarter of 2024, about 347,000 person-quarter records in total, of which roughly 278,000 working-age observations with non-missing education enter the baseline estimation sample (the partially treated transition quarter 2022Q2 is excluded; see Section 5). I add the four quarters of 2025 for the out-of-

sample validation exercise. All statistics use the module’s sampling weights; the treatment of standard errors is discussed in Section 5.

I restrict the sample to individuals of working age, defined as ages 14 to 65,⁴ and I drop observations with missing education. My main wage analysis is further restricted to private-sector wage earners,⁵ for whom the minimum wage is the relevant statutory floor, while the employment and participation outcomes are defined over the working-age population and the formality and self-employment outcomes over employed private-sector workers.

4.2 Education and the definition of skill groups

The treatment and comparison groups are defined by educational attainment, recorded in ENAHO variable `p301a`, the highest level of schooling completed. I validated the coding of this variable against the weighted distribution of attainment in the data; it corresponds to the standard INEI classification, ranging from no schooling through postgraduate study. I define *low-skilled* workers as those with at most complete secondary schooling (no education, initial, primary, or secondary), and *high-skilled* workers as those with any tertiary schooling (non-university higher, university, or postgraduate). I exclude the small residual category of special education, which is not ordered on the skill dimension, and observations with missing education.

This partition has three attractive features. First, it is a bright line in the Peruvian labor market: completion of tertiary schooling is the main credential that separates workers who compete for jobs paying near the minimum wage from those who do not. Second, it splits the working-age population into groups of comparable size, roughly two thirds low-skilled and one third high-skilled, which gives adequate statistical power on both sides. Third, and most important for identification, the two groups differ sharply in their exposure to the minimum wage. As Table 1 shows, in the pre-reform period the median monthly wage of a low-skilled dependent employee is close to the statutory floor, whereas the median high-skilled employee earns well above it. The classification follows a long line of work that treats education as a primary determinant of where the minimum wage bites (Lemos, 2009; Katzkowicz et al., 2021).

⁴Fourteen is the minimum legal working age in Peru; 65 is the conventional upper bound of the working-age population.

⁵White- and blue-collar employees and domestic workers, ENAHO occupational-category variable `p507` equal to 3, 4, or 6; domestic workers have been entitled to the minimum wage since Law 31047 (2020). Employers, own-account workers, and unpaid family workers are treated as separate categories, and public-sector workers are excluded from job-level outcomes because their pay is set by separate scales.

4.3 Outcome variables

The outcomes fall into three groups. On *pay*, ENAHO records wage earners’ pay per pay period together with its frequency; because over half of low-education wage earners are paid daily, weekly, or fortnightly—against fifteen percent of high-education wage earners—I convert all payments to monthly equivalents using the frequency variable before any comparison across groups (Appendix A details the conversion, which matches INEI’s own annualization). The real hourly wage divides this monthly-equivalent labor income by monthly hours, deflated by the Lima consumer price index at the month the income refers to, in December 2021 soles, and winsorized at the first and last half-percentiles; real monthly earnings is the same numerator without the hours adjustment. On *quantities*, employment and labor force participation are indicators defined over the working-age population, and weekly hours is hours worked in the main occupation. On *composition*, formal employment and self-employment are defined among employed private-sector workers, and an indicator for being paid below the statutory minimum in force in the income reference month is defined among private wage earners; the last is a direct measure of the bite of and compliance with the policy.

A measurement issue arises for informality. INEI’s official informal-employment indicator, `ocupinf`, is present in the 2021 through 2023 files but is not released in the 2024 and 2025 files. Because my study window extends through 2024, I reconstruct a consistent informality indicator from underlying primitives that are available in every year: pension affiliation, the possession of a formal labor contract, the registration status of the productive unit, and the category of employment. I validate the reconstruction against the official `ocupinf` in 2021 through 2023, where both are available, and obtain agreement of about 88 percent at the worker level, with an implied informality rate of 74.9 percent against the official 79.1 percent. I use the official indicator wherever it exists and the reconstruction only for 2024 and 2025, and I report a robustness check that restricts the formality analysis to the years covered by the official measure. Full details of the construction are in Appendix A.

4.4 Descriptive statistics

Table 1 reports weighted means of the main variables by skill group in the pre-reform period. The two groups differ in the expected ways. Low-skilled workers are older on average, more likely to be married and rural, and have far lower wages. The employment rate is similar across groups, but the composition of employment differs starkly: low-skilled workers are much more likely to be informal and self-employed, and far more likely to earn below the statutory minimum. Among private wage earners, 57 percent of the low-skilled were paid below the *new* minimum of 1,025 soles on the eve of the reform, against 40 percent of the

high-skilled—the exposure gap on which my design rests, though the substantial exposure of the comparison group also means the design estimates a relative rather than an absolute effect. The high informality of the low-skilled group, 87 percent against 53 percent for the high-skilled, is central to interpreting the results: for most low-skilled workers the statutory floor is not directly enforced, so the margin along which the labor market can adjust is the allocation of workers across formal and informal arrangements rather than the level of pay within formal jobs.

Table 1: Descriptive statistics by skill group, pre-reform period

	Low-skilled ($\leq$ sec. complete)	High-skilled ($\geq$ higher)	Difference
Age	35.92	34.65	1.27
Female	0.50	0.50	0.00
Urban	0.76	0.93	-0.17
Married	0.53	0.41	0.12
Years of education	8.57	14.47	-5.90
Labour force participation	0.73	0.80	-0.07
Employed	0.69	0.73	-0.04
Wage employee (incl. domestic)	0.29	0.48	-0.19
Self-employed	0.39	0.24	0.15
Formal (if employed)	0.13	0.47	-0.34
Informal (if employed)	0.87	0.53	0.34
Weekly hours (if employed)	39.74	41.44	-1.70
Real hourly wage (S/)	5.74	9.08	-3.34
Real monthly earnings (S/)	904.30	1,755.12	-850.82
Below MW (wage earners)	0.43	0.19	0.24
Observations	65,954	27,278	

Notes: Weighted means using ENAHO survey weights, working-age individuals (14–65) in the pre-reform quarters (2021Q1–2022Q1). Low-skilled: education at most complete secondary ($\text{p301a} \leq 6$). High-skilled: any tertiary education ($\text{p301a} \geq 7$). Wage-earner variables (hourly wage, below MW) are conditional on being a private-sector wage earner (employees and domestic workers, monthly-equivalent earnings); hours and formality are conditional on employment. Observation counts are unweighted. The below-MW row uses the statutory floor in force in the income reference month (930 soles throughout the pre-reform window); the exposure shares relative to the NEW floor (57 vs. 40 percent) discussed in the text use 1,025 soles.

Figure 2 plots the weighted quarterly means of the main outcomes by skill group over the study window, with the reform marked. The raw series already hint at the results that follow: the wage series of the two groups move in parallel throughout, while the formality and self-employment series begin to diverge around the reform. The figure also makes visible a fact that disciplines the analysis: in the employment panel it is the *high*-education series

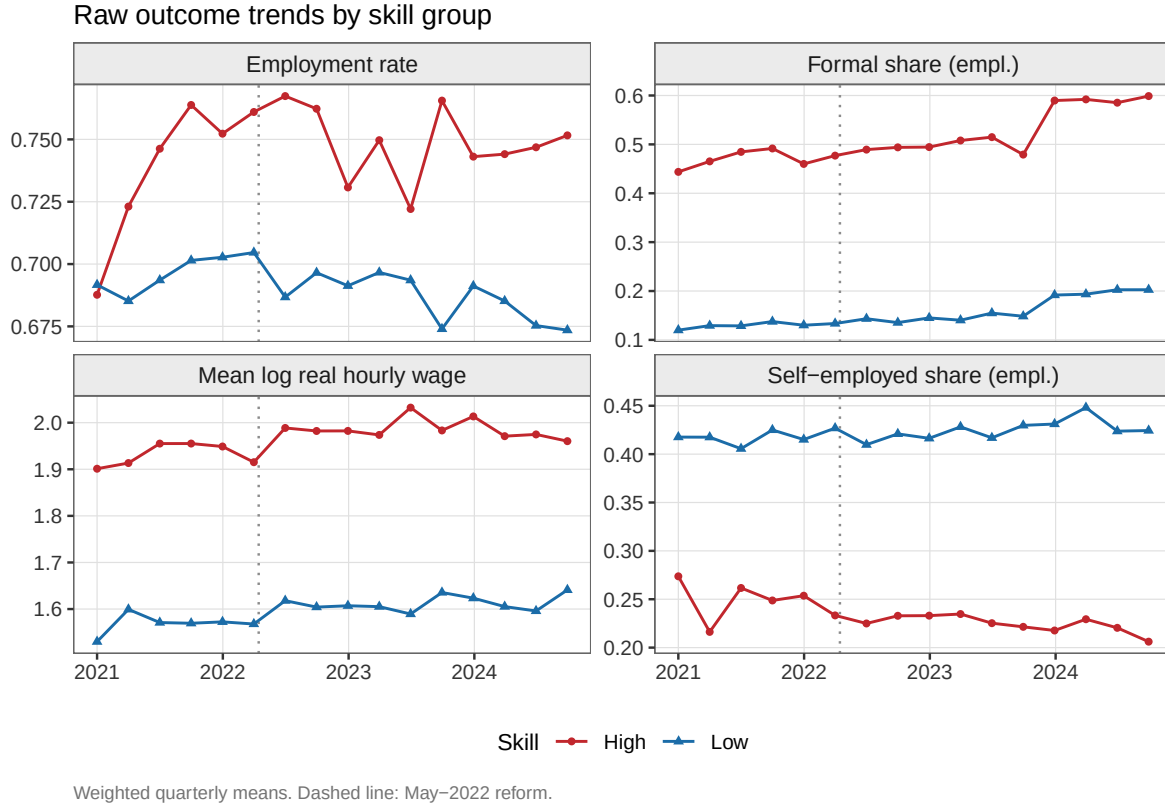

Figure 2: Raw outcome trends by skill group, 2021–2024. Weighted quarterly means for low- and high-skilled workers. The dashed vertical line marks the May 2022 reform.

that swings—rebounding sharply through 2021 and oscillating thereafter—while the low-education series is comparatively flat, so any employment “effect” in the education contrast is driven largely by movements of the comparison group; this is part of why Section 6 declines to interpret that margin causally. These are unconditional means; the regression analysis that follows adjusts for composition and seasonality.

Figure 3 displays the regional variation in the bite of the minimum wage, measured by the Kaitz index, the ratio of the new minimum to the pre-reform median monthly-equivalent wage of private wage earners in each department. The index ranges from about 0.79 in Ica to about 1.97 in Huánuco, and it exceeds one in eighteen of the twenty-five departments, so that in much of the country the new minimum exceeds the median wage. This variation is predetermined with respect to the reform and provides the basis for the triple-difference and continuous-intensity checks in Section 7.

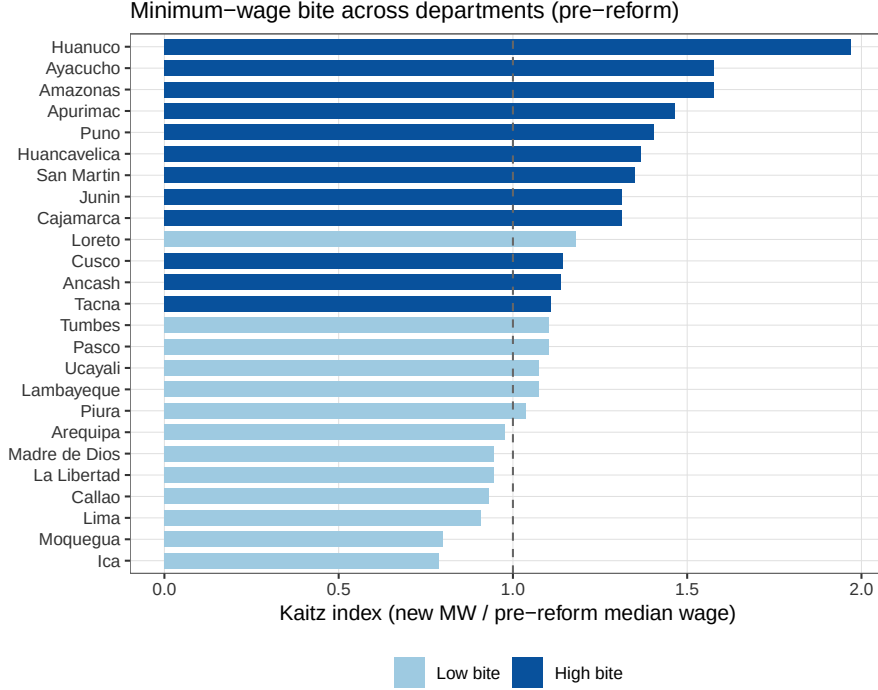

Figure 3: Regional variation in the bite of the minimum wage. The Kaitz index is the ratio of the new minimum wage (1,025 soles) to the department’s median monthly-equivalent wage of private wage earners in the pre-reform quarters. Departments above the dashed line have a median wage below the new minimum.

5 Empirical strategy

5.1 Potential outcomes and the estimand

Let i index individuals, $g \in \{\text{Low}, \text{High}\}$ their skill group, and t the quarter. The reform becomes effective in the second quarter of 2022, which I denote t^* ;⁶ define the post-reform indicator $\text{Post}_t = \mathbf{1}\{t \geq t^*\}$ and the treatment indicator $\text{Low}_i = \mathbf{1}\{g_i = \text{Low}\}$. Following the potential-outcomes framework, let $Y_{it}(1)$ and $Y_{it}(0)$ denote the outcome of individual i in quarter t with and without the reform being in force. The parameter of interest is the average effect of the reform on the low-skilled, relative to the counterfactual in which they had experienced the same evolution as the high-skilled,

$$\text{ATT} = \mathbb{E}[Y_{it}(1) - Y_{it}(0) \mid \text{Low}_i = 1, t \geq t^*]. \quad (1)$$

⁶Because the reform took effect on 1 May, the second quarter of 2022 contains one pre-reform and two post-reform months, and reported incomes refer to the month before the interview, so even May interviews report pre-reform (April) earnings. I therefore exclude 2022Q2 from the baseline as a partially treated transition quarter and restore it in a robustness check; the first post-reform quarter in the baseline is 2022Q3.

The data are repeated cross-sections rather than a panel, so the object is identified from comparisons of group means over time rather than from within-person changes.

Because Peru’s minimum wage is national and changes on a single date, there is no variation in treatment *timing*; every worker is exposed to the same policy at the same moment. Identification instead rests on variation in the *intensity* of exposure across skill groups. The design is therefore a canonical two-group difference-in-differences with many periods, not a staggered-adoption design. This distinction matters for the choice of estimator. The recent econometric literature has shown that the two-way fixed-effects estimator can be badly biased when treatment timing is staggered and effects are heterogeneous (Goodman-Bacon, 2021; de Chaisemartin and D’Haultfuille, 2020; Sun and Abraham, 2021; Callaway and Sant’Anna, 2021). With a common treatment date, however, these problems do not arise: the two-way fixed-effects estimator and its event-study analog recover a convex, properly weighted average of treatment effects (Roth et al., 2023; Baker et al., 2022). I nonetheless report the doubly robust estimator of Sant’Anna and Zhao (2020) as a complementary building block.

5.2 Estimating equations

My baseline specification is the two-way fixed-effects difference-in-differences model

$$Y_{idt} = \beta (\text{Low}_i \times \text{Post}_t) + \gamma \text{Low}_i + \lambda_t + \mu_d + X'_{it}\theta + \varepsilon_{idt}, \quad (2)$$

where d denotes the department, λ_t are quarter fixed effects, μ_d are department fixed effects, and X_{it} is a vector of controls comprising age, its square, sex, an urban indicator, marital status, and years of education (which captures variation in attainment within skill groups). The coefficient β is the difference-in-differences estimate. The quarter fixed effects absorb any shock common to both skill groups in a given quarter, including aggregate inflation, so that estimates in logs are invariant to whether wages are expressed in nominal or in nationally deflated real terms. Observations are weighted by the survey weights, and standard errors are clustered by department.

To trace the dynamics of the effect and to test the identifying assumption, I estimate the dynamic event-study specification

$$Y_{idt} = \sum_{k \neq -1} \beta_k (\text{Low}_i \times \mathbf{1}\{t - t^* = k\}) + \gamma \text{Low}_i + \lambda_t + \mu_d + X'_{it}\theta + \varepsilon_{idt}, \quad (3)$$

where k indexes quarters relative to the reform and the quarter immediately before the

reform ($k = -1$, the first quarter of 2022) is the omitted reference. The coefficients β_k for $k < 0$ measure differential pre-trends between the skill groups and provide a direct test of parallel trends; the coefficients for $k \geq 0$ trace the path of the effect.

5.3 Identifying assumptions and threats

Identification of the ATT from equation (2) requires that, absent the reform, the outcomes of low- and high-skilled workers would have followed parallel paths, conditional on the controls and fixed effects. Three threats deserve attention.

First, *differential trends*. Education is correlated with sector, region, and formality, and the two skill groups could have been on diverging paths for reasons unrelated to the minimum wage. I assess this directly through the pre-reform event-study coefficients and a joint test of their equality to zero, and I probe robustness to department-specific linear trends. Because my window opens in the depth of the pandemic recovery, when the employment of low- and high-skilled workers rebounded at different rates, I pay particular attention to the first quarter of 2021 and report specifications that drop it.

Second, *sensitivity to residual violations*. Even when pre-trends are statistically flat, they need not be exactly zero. I therefore report the sensitivity analysis of Rambachan and Roth (2023), which asks how large a post-reform violation of parallel trends, relative to the largest violation observed before the reform, would be needed to overturn each conclusion.

Third, *spillovers and general equilibrium*. If the reform displaces low-skilled workers into the informal sector, it may indirectly depress wages there, and if high-skilled workers are imperfect substitutes their outcomes could also move, contaminating the comparison group. I cannot rule this out, and I interpret the estimates as relative effects. The comparison group is not entirely unexposed: 40 percent of high-skilled private wage earners were paid below the new floor before the reform, against 57 percent of the low-skilled. To first order this imperfect exposure attenuates the estimates toward zero—the design identifies the effect of the seventeen-point exposure *gap*, so it understates the effect on the fully exposed—but I acknowledge that it also makes the estimates relative objects rather than absolute ones. For this reason I complement the education contrast with a continuous regional-exposure design that does not rely on the comparison group at all (Section 7).

5.4 Inference

The treatment is assigned at a coarse level, the skill group, which raises the standard concern that conventional standard errors overstate precision (Bertrand et al., 2004). I address this

in several complementary ways. My baseline clusters by department,⁷ which allows arbitrary within-department correlation across individuals and quarters; I report an alternative that clusters by department and skill group; and I apply the bias-reduced CR2 small-sample correction of Pustejovsky and Tipton (2018) to department-level collapsed cells, where it is computationally feasible. Because these corrections may still be optimistic with a two-group design, I complement them with randomization inference at the department level, permuting the regional bite of the minimum wage across departments to construct an exact null distribution for the exposure-intensity design.

6 Main results

6.1 The reallocation of low-skilled employment

The central result of the paper is that the 2022 reform shifted the composition of low-skilled employment away from formal wage work and toward self-employment, without raising the pay of the workers it targeted. I present the compositional evidence first, then the first-stage evidence on where the floor binds, and the wage evidence third.

The estimated effect on the probability of formal employment among employed private-sector workers is -0.046 (column 1 of Table 2), a decline of 4.6 percentage points for low-skilled relative to high-skilled workers—about a fifth of the group’s 23 percent baseline formality rate—an arithmetically large semi-elasticity (about -2 with respect to the 10.2 percent increase, column 4 of Table 2) that reflects how small the formal base is for this group rather than an implausibly elastic response. The estimate is precisely estimated under department clustering, and the pre-trend test does not reject parallel trends ($p = 0.15$); Section 7 takes the residual-drift concern seriously and shows that drift-adjusted magnitudes remain economically large and coincide with the synthetic-DiD estimate. The event study in Figure 5 shows the relative formality of the low-skilled dropping immediately after the reform, by around four percentage points within a year, and persisting. Mirroring this, the probability of self-employment rises by 3.6 percentage points. The self-employment series, unlike formality, does show a rejected pre-trend test ($p = 0.003$), driven by one elevated quarter in mid-2021, so I lean on the formality margin as the cleaner of the two and treat the self-employment estimate as its corroborating mirror image. Weekly hours in the main occupation rise modestly and full-time status falls slightly, consistent with a shift toward

⁷The 25 clusters are Peru’s 24 departments plus the Constitutional Province of Callao. With few clusters, conventional cluster-robust standard errors can understate uncertainty, which motivates the additional corrections below.

own-account work, where hours are less standardized.

Two independent pieces of evidence support a causal reading of this reallocation. First, it scales with exposure: as Section 8 shows, the formality decline and the self-employment rise are both larger in the departments where the new floor cuts deeper into the pre-reform wage distribution. Second, a continuous-exposure design in the spirit of Card (1992), which discards the education contrast altogether and relates outcomes to the standardized pre-reform regional Kaitz index, yields the same picture: a one-standard-deviation higher regional bite is associated with a 1.8 percentage-point larger decline in formality and a 1.0 point larger rise in self-employment after the reform, estimates that survive design-based randomization inference at the department level (Section 7). Taken together these results describe a reallocation of low-skilled workers away from formal salaried jobs and toward own-account work, the classic informalization margin emphasized by Jaramillo and López (2006) for Peru and by Ham (2018) for Honduras.

Table 2: Difference-in-differences estimates of the 2022 minimum-wage reform

Outcome	(1) TWFE DiD	(2) Doubly robust	(3) Pre-trend p	(4) Elasticity
Log real hourly wage	-0.021 (0.012) $N = 69,534, \bar{y} = 1.744$	-0.056 (0.137)	0.001	-0.20
Log real monthly earnings	-0.010 (0.013) $N = 70,691, \bar{y} = 6.901$	-0.047 (0.097)	0.079	-0.10
Employment	-0.025*** (0.006) $N = 278,064, \bar{y} = 0.707$	0.020 (0.037)	0.000	-0.35
Labour force participation	-0.008* (0.004) $N = 278,064, \bar{y} = 0.744$	-0.015 (0.034)	—	-0.10
Formal employment	-0.046*** (0.007) $N = 181,317, \bar{y} = 0.228$	0.006 (0.040)	0.148	-1.99
Self-employment	0.036*** (0.006) $N = 181,317, \bar{y} = 0.389$	0.046 (0.045)	0.003	0.91
Weekly hours	0.556** (0.249) $N = 179,111, \bar{y} = 40.655$	-0.424 (0.872)	0.034	0.13
Paid below the MW	-0.006 (0.007) $N = 70,691, \bar{y} = 0.352$	-0.007 (0.039)	0.128	-0.16

Notes: Each row is a separate regression on ENAHO 2021Q1–2024Q4, excluding the partially treated transition quarter 2022Q2. Column (1) reports the two-way fixed-effects DiD coefficient on $\text{Low} \times \text{Post}$ from equation (2), with department and quarter fixed effects and controls (age, age squared, sex, urban, marital status, years of education). Column (2) reports the doubly robust DiD estimator of Sant’Anna and Zhao (2020) collapsing to pre/post; its standard errors are clustered by department using the estimator’s influence function. Column (3) is the p -value of a joint test that the pre-reform event-study interactions are zero. Column (4) converts the column-(1) estimate into an elasticity with respect to the 10.2 percent minimum-wage increase (for level outcomes, relative to the baseline mean $\bar{y}$). Wage outcomes are for private-sector wage earners (employees and domestic workers, monthly-equivalent earnings); formality, hours, and self-employment are for private-sector workers. Standard errors clustered by department (25 clusters) in parentheses; all estimates are weighted by ENAHO survey weights. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

6.2 The first stage: where the floor is enforced, it binds

Where does the statutory floor actually bind? Pinning this down first disciplines the interpretation of the pay results that follow. Table 3 and Figure 4 examine the earnings distribution of *formal* private wage earners, the segment where enforcement is concentrated, in symmetric

three-quarter windows around the reform. Before the reform, 14 percent of low-skilled formal wage earners are paid within 2.5 percent of the old floor of 930 soles—a visible spike, in the manner of Cengiz et al. (2019) and Engbom and Moser (2022). After the reform the spike migrates essentially completely: the mass at 930 collapses to under 2 percent and an almost identical spike, 14 percent, appears at the new floor of 1,025. Formal-sector employers, in other words, complied with the new minimum.

The compliance response splits exactly along the enforcement boundary. Panel B of Table 3 estimates the DiD for an indicator of pay below 1,025 soles, holding the threshold fixed in all periods. Among formal wage earners the share below the new floor falls by five percentage points for low- relative to high-skilled workers (marginally significant, $p = 0.10$); among *informal* wage earners it *rises* by four percentage points ($p = 0.002$)—informal pay drifted further below a floor that does not apply in practice. The two responses offset in the pooled fixed-threshold estimate (last row of Panel B), which is also why the statutory below-minimum indicator of Table 2 shows no change. Together with the reallocation results, this evidence describes a coherent two-sector adjustment: the floor binds and is honored inside the formal sector, formal employment of the affected group contracts, and the displaced margin reappears as self-employment and informal work whose pay the floor does not reach.

Table 3: First stage: spike migration and compliance at the wage floor

	Pre window	Post window	
<i>Panel A: share of formal wage earners within $\pm 2.5\%$ of each floor</i>			
All formal wage earners			
At the old floor (930)	0.114	0.011	
At the new floor (1,025)	0.052	0.117	
Low-skilled formal wage earners			
At the old floor (930)	0.142	0.016	
At the new floor (1,025)	0.064	0.140	
<i>Panel B: DiD on the share paid below 1,025 (fixed threshold)</i>			
	DiD	(s.e.)	Pre-trend p
Formal wage earners	-0.050	(0.030)	0.099
Informal wage earners	0.042***	(0.012)	0.068
All wage earners	0.025	(0.021)	0.007

Notes: Panel A reports the weighted share of formal private wage earners (monthly-equivalent pay) within ± 2.5 percent of each statutory floor, in symmetric three-quarter windows before (2021Q3–2022Q1) and after (2022Q3–2023Q1) the reform. Panel B reports Low $\times$ Post DiD estimates for an indicator of monthly-equivalent pay below 1,025 soles (threshold held fixed in all periods), by formality status, with department-clustered standard errors and the joint pre-trend p -value in the last column. ENAHO survey weights throughout. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

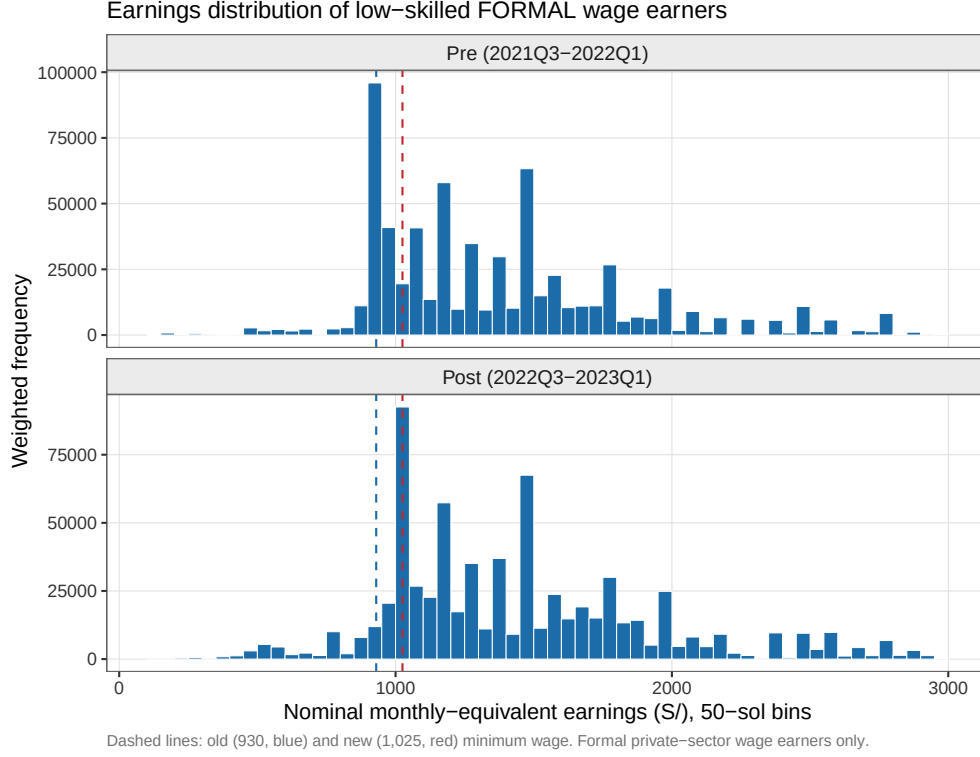

Figure 4: Spike migration at the wage floor among low-skilled formal private wage earners. Weighted histograms of nominal monthly-equivalent earnings (50-sol bins) in symmetric three-quarter windows before (2021Q3–2022Q1) and after (2022Q3–2023Q1) the reform. Dashed lines mark the old (930) and new (1,025) minimum wage.

6.3 The wage response

If covered employers complied with the new floor, did the pay of the low-skilled group rise as a whole? On average, no. The coefficient on the interaction of the low-skill indicator with the post-reform indicator is -0.021 for the log real hourly wage, with a standard error of 0.012 : negative, marginally insignificant, and inconsistent with the reform having lifted relative pay. The estimate for log monthly earnings is similarly null. I am deliberately careful about how much this regression can bound, for a transparent reason reported in column (3) of Table 2: the joint pre-trend test for the hourly wage rejects ($p = 0.001$), driven by a single positive spike in 2021Q2 ($k = -4$) rather than by a systematic trend. Once violations of parallel trends are allowed, the education contrast cannot pin the wage effect tightly in either direction: under the relative-magnitudes restriction of Rambachan and Roth (2023) the robust interval at exact parallel trends reaches $+2.9$ percent, and under linear extrapolation of the (gently declining) pre-trend even larger positive values are admissible. I therefore do not rest the no-lift conclusion on the average wage regression. It rests on the two pieces of pay evidence whose diagnostics are clean and which do not depend on the

education pre-trend.

First, the share of wage earners paid below the statutory floor—35 percent of low-skilled wage earners at baseline—does not fall after the reform (the estimate is -0.006 with $p = 0.45$, and its pre-trends are flat, $p = 0.13$). If firms had complied with the new floor for the marginal worker, this share would have dropped mechanically. Second, the earnings distribution in Figure 6 shows visible mass near the old minimum before the reform but no appreciable migration of that mass toward the new floor afterward, reflecting the pervasive non-compliance documented in Section 4; the unconditional-quantile estimates of Section 8 likewise show no gain at any decile, including the bottom ones where an enforced floor must compress the distribution. The doubly robust estimator of Sant’Anna and Zhao (2020) in column (2) is negative and imprecise for wages and insignificant for every other outcome once its standard errors are clustered by department.⁸

That the reform failed to lift wages at the bottom is not surprising in this setting: once inflation is netted out the real value of the floor rose little, most low-skilled workers are informal or self-employed, and enforcement is thin, so the statutory minimum constrains pay for only a minority. The absence of a pay response contrasts with the “lighthouse” pattern that Jiménez (2023) finds for the 2016 reform. I take up these mechanisms, and the contrast with earlier reforms, in Section 9.

6.4 The level of employment

The estimated effect on the overall employment rate is -2.5 percentage points, which would imply an employment elasticity with respect to the minimum wage of about -0.35 , more than twice the largest estimates in the earlier Peruvian literature (Céspedes, 2005). I do not give this estimate a causal interpretation, for three reasons documented in Section 7: the employment series carries a clear differential pandemic-recovery pre-trend concentrated in early 2021 (pre-trend $p < 0.001$); in-time placebo reforms placed in the pre-period produce “effects” of similar magnitude and significance; and, unlike the compositional margins, the employment effect does not scale with regional exposure—if anything it is smaller in high-bite departments. Once 2021Q1 is excluded the point estimate roughly halves, and it does not survive the more conservative inference procedures. I therefore treat the employment-level result as reflecting differential recovery dynamics rather than the minimum wage, and place the interpretive weight on the compositional shift, whose diagnostics are clean.

⁸The doubly robust estimator collapses the data to a single pre- and post-reform period and omits department fixed effects, so it is both less comparable to the two-way fixed-effects specification and much less precise under department clustering; I report it as a complementary check rather than as the preferred estimate.

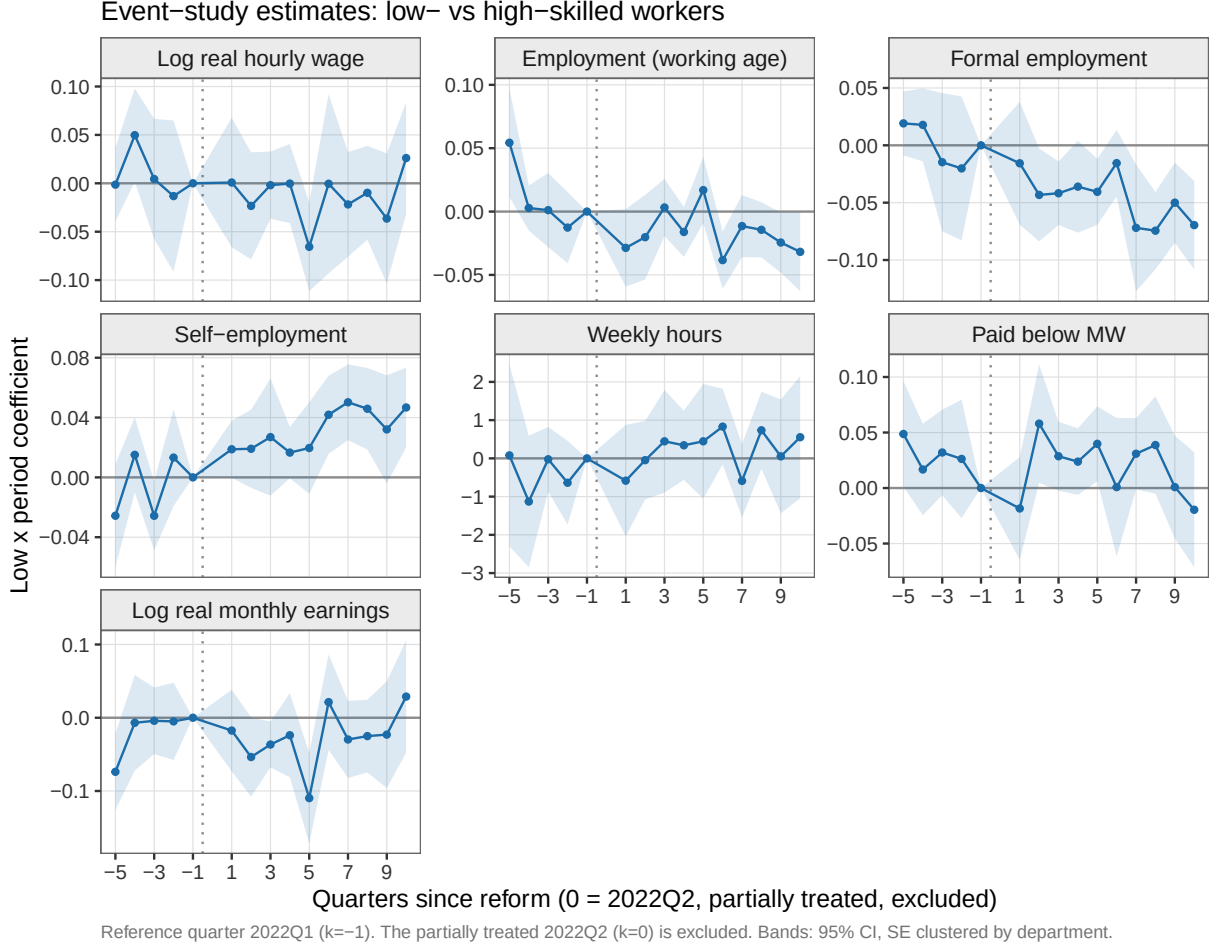

Figure 5: Event-study estimates of the 2022 reform. Each panel plots the coefficients β_k on the interaction of the low-skill indicator with quarter indicators from equation (3), relative to the omitted quarter 2022Q1 ($k = -1$). The partially treated transition quarter 2022Q2 ($k = 0$) is excluded. Shaded bands are ninety-five percent confidence intervals with standard errors clustered by department.

7 Robustness and inference

This section subjects the main results to a battery of specification, inference, and design checks, and then to an out-of-sample replication. The overall message is that the compositional results—the decline in formality and the rise in self-employment—are the most robust findings, corroborated by an independent continuous-exposure design under randomization inference; the wage evidence consistently shows no pay gain but carries a pre-trend caveat; and the employment-level result fails its diagnostics and should not be read causally.

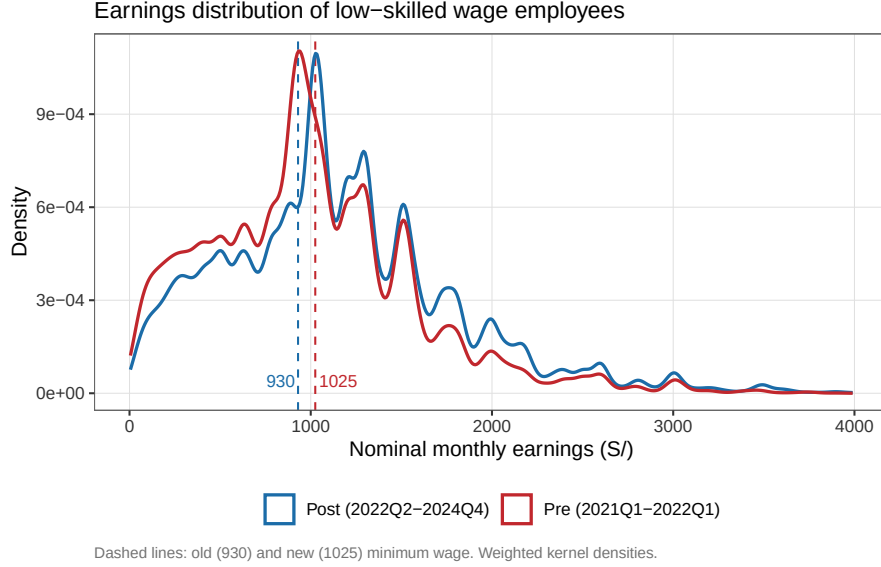

Figure 6: Earnings distribution of low-skilled wage earners, before and after the reform. Weighted kernel densities of nominal monthly-equivalent earnings (private-sector employees and domestic workers), with the old (930) and new (1,025) minimum wage marked by dashed lines.

7.1 Specification robustness

Table 4 reports the $\text{Low} \times \text{Post}$ coefficient for the four headline outcomes under ten alternative specifications: dropping the controls, dropping the pandemic quarter of early 2021, adding department-specific linear trends, restricting to prime-age workers, using an alternative education cutoff that removes the categories at the boundary between the two groups, adding occupation and industry fixed effects, clustering by department and skill, restoring the partially treated transition quarter 2022Q2, excluding agriculture (which is covered by the separate agrarian labor regime of Ley 31110 rather than the general minimum wage), and adding public-sector workers back into the job-conditional samples. The formality and self-employment estimates are stable in sign and magnitude throughout, moving within a narrow band. The wage estimate is negative or null in every specification and never significantly positive. The employment estimate, by contrast, attenuates noticeably when the pandemic quarter is dropped or when department-specific trends are included, which reinforces my reluctance to interpret it causally.

Table 4: Specification robustness of the DiD estimates

Specification	Log hourly wage	Employment	Formal empl.	Self-employment
Baseline	-0.021 (0.012) [69,534]	-0.025*** (0.006) [278,064]	-0.046*** (0.007) [181,317]	0.036*** (0.006) [181,317]
No controls	-0.008 (0.012) [69,534]	-0.021*** (0.006) [278,064]	-0.042*** (0.007) [181,317]	0.042*** (0.006) [181,317]
Drop 2021Q1 (pandemic)	-0.023* (0.012) [65,279]	-0.014*** (0.005) [259,135]	-0.042*** (0.008) [168,908]	0.031*** (0.005) [168,908]
Department linear trends	-0.022* (0.012) [69,534]	-0.017*** (0.006) [278,064]	-0.040*** (0.007) [181,317]	0.034*** (0.006) [181,317]
Prime age (25–55)	-0.030* (0.015) [46,021]	-0.023*** (0.004) [161,115]	-0.042*** (0.008) [119,540]	0.029*** (0.007) [119,540]
Alternative education cutoff	-0.015 (0.012) [40,526]	-0.039*** (0.007) [186,263]	-0.065*** (0.006) [117,174]	0.050*** (0.007) [117,174]
Occupation & industry FE	-0.007 (0.011) [69,534]	-0.016*** (0.003) [213,810]	-0.036*** (0.006) [181,317]	0.027*** (0.005) [181,317]

Low-skilled group linear trend	-0.021 (0.019) [69,534]	-0.005 (0.008) [278,064]	-0.004 (0.010) [181,317]	0.006 (0.009) [181,317]
Include transition quarter (2022Q2)	-0.018 (0.012) [74,310]	-0.025*** (0.005) [296,954]	-0.044*** (0.007) [193,762]	0.035*** (0.006) [193,762]
Exclude agriculture (agrarian regime)	-0.022* (0.012) [53,755]	– [–]	-0.038*** (0.007) [114,212]	0.028*** (0.005) [114,212]
Include public-sector workers	-0.002 (0.010) [87,033]	– [–]	-0.037*** (0.008) [200,383]	0.030*** (0.006) [200,383]

Notes: Each cell is the Low $\times$ Post DiD coefficient (standard error clustered by department below; sample size in brackets) for the outcome in the column heading, under the specification in the row; all estimates are weighted by ENAHO survey weights, and Log hourly wage denotes the log real hourly wage. The baseline is equation (2), which excludes the partially treated 2022Q2. The alternative education cutoff defines low-skilled as at most incomplete secondary and high-skilled as at least complete non-university tertiary, dropping the boundary categories. The agriculture exclusion and the public-sector inclusion apply to job-conditional outcomes only (industry and sector are undefined for non-workers). * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

7.2 Inference

Because the treatment contrast varies only across two education groups, conventional department clustering does not by itself deliver design-based inference for the Low $\times$ Post coefficient, and I therefore report a menu of progressively more demanding procedures. Table 5 collects the evidence. Columns (1) through (3) report p -values for the baseline effect under department clustering (25 clusters), department-by-skill clustering (50 clusters), and the CR2 small-sample correction of Pustejovsky and Tipton (2018) applied to collapsed cells in the spirit of Bertrand et al. (2004)—here at the department $\times$ group $\times$ period level, the finest aggregation at which the CR2 correction is computationally feasible. The formality and self-employment effects remain highly significant under both clustering schemes; under the collapsed-cell CR2 procedure, which is deliberately conservative and low-powered with twenty-five departments, self-employment remains marginally significant and formality does not. The employment effect loses significance under everything beyond simple department clustering. Because a permutation test of the two-group contrast is undefined, design-based randomization inference is conducted for the continuous-exposure design instead, where the assignment being permuted—the regional bite—has twenty-five values: column (4) reports these p -values, which belong to the column-(5) estimates, not to the education contrast.⁹

Table 5: Inference robustness, design robustness, and out-of-sample validation

Outcome	(1) Dept.	(2) Dept. $\times$ skill	(3) CR2	(4) RI (continuous)	(5) Continuous	(6) 2025 reform
Log hourly wage	0.106	0.126	0.854	0.029	0.017 (0.012)	0.002 (0.011)
Employment	0.000	0.210	0.507	0.003	-0.034*** (0.012)	-0.002 (0.005)
Formal empl.	0.000	0.000	0.244	0.000	-0.018*** (0.003)	-0.001 (0.008)
Self-employment	0.000	0.000	0.093	0.024	0.010** (0.004)	-0.014** (0.006)

Notes: Columns (1)–(3) report p -values for the baseline Low $\times$ Post effect under, respectively, department clustering (25 clusters), department $\times$ skill clustering (50 clusters), and the CR2 small-sample correction (Pustejovsky and Tipton, 2018) applied to department-level collapsed cells. Column (4) reports the randomization-inference p -value for the CONTINUOUS-exposure design of column (5) – not for the two-group Low $\times$ Post contrast – obtained by permuting the 25 regional Kaitz indices across departments (2,000 draws). Column (5) reports the continuous-exposure estimate, the coefficient on Post $\times$ (standardized department Kaitz index), with department-clustered standard errors in parentheses. Column (6) reports the Low $\times$ Post DiD estimate for the January-2025 reform (window 2024–2025), with department-clustered standard errors in parentheses. Log hourly wage denotes the log real hourly wage; all estimates are weighted by ENAHO survey weights. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

⁹A wild cluster bootstrap in the spirit of Cameron et al. (2008) is not available for survey-weighted estimation, so the CR2 and randomization procedures play that role here.

7.3 Design robustness: bite intensity and triple differences

My identification rests on differential exposure by education, but the minimum wage also bites differentially across regions, and this provides an independent source of variation that does not rely on the education contrast at all. Column (5) of Table 5 reports a continuous-exposure specification in the spirit of Card (1992), which relates outcomes to the standardized pre-reform department Kaitz index interacted with the post indicator. The results corroborate the skill-based design on the compositional margins: in departments where the minimum wage bites harder, formal employment falls by 1.8 percentage points more per standard deviation of exposure ($p < 0.001$; randomization $p < 0.001$) and self-employment rises by 1.0 point more ($p = 0.02$; randomization $p = 0.02$) after the reform. Employment also declines with exposure in this design, though I discount that margin for the reasons above. Wages show no significant response. A triple-difference specification that interacts the skill contrast with an indicator for high-bite departments is not statistically significant for any outcome (Appendix Table 6), which I read as a lack of power in the coarse binary regional split rather than as evidence against the mechanism, given that the continuous version is informative and that the subgroup estimates in Section 8 move in the expected direction.

Three further design checks discipline this corroboration (Appendix Tables 8 and 9). First, the regional design passes its own leads diagnostic exactly where it matters: joint tests of the pre-reform quarter $\times$ exposure interactions do not reject for formality ($p = 0.84$), self-employment ($p = 0.20$), or wages ($p = 0.24$), and reject only for employment ($p = 0.002$), consistent with everything else about that margin. Second, in the spirit of full transparency I also estimate finer, cell-level fraction-affected designs (Card, 1992; Clemens and Wither, 2019), with exposure measured within department $\times$ skill $\times$ age cells; these fail their leads diagnostics in both variants—fine-grained exposure is confounded with the cells’ heterogeneous pandemic recoveries, and the between-floors variant even flips signs because cells with mass between the two floors are precisely the semi-formal cells that recovered fastest. I therefore treat the department as the credible level for exposure variation and report the cell designs in the appendix rather than suppressing them. Third, the reallocation is broad-based across sectors: the formality decline appears in the covered high-bite sectors, in other private sectors, and in agriculture alike. The agricultural estimate is not a falsification failure, because the agrarian regime’s daily remuneration is indexed to the RMV and therefore rose with the reform; Peru leaves no large sector’s floor unchanged, which is why coverage contrasts cannot be sharp here. An occupation-level dose response (exposure measured as the pre-reform share of the occupation’s wage earners below the new floor) shows larger declines in sub-floor pay and, suggestively, relative wage gains in more-exposed occupations, though occupation

is measured post-treatment and I read that panel as descriptive.

As a final design check I estimate synthetic difference-in-differences (Arkhangelsky et al., 2021) on department-by-quarter cells, treating high-bite departments as treated from 2022Q3 and letting the estimator re-weight low-bite departments to reconstruct their pre-reform path (Appendix Table 11). The estimates are directionally consistent with the reallocation—formality falls and self-employment rises, whether the outcome is the low-education mean or the low-minus-high skill gap—with magnitudes about half the TWFE estimates and precision limited by twenty-five aggregate units; the formality decline in low-education means is significant at five percent under the jackknife.

7.4 Selection and power

Because the reform moved workers out of the wage-earner sample, the wage DiD conditions on an endogenous population. Appendix Table 10 bounds the resulting bias with the trimming approach of Lee (2009): the reform reduced low-skilled wage-sample inclusion by 2.1 percentage points (7.6 percent of the baseline rate), and trimming the low $\times$ post wage distribution by that fraction from either tail brackets the unconditional 2×2 wage DiD between -0.10 and $+0.10$. Selection alone could therefore mask wage effects of up to ten log points in either direction, a candid statement of what the wage evidence can and cannot rule out; the compliance and bunching evidence of Section 6, which conditions only on formality status, is not subject to this concern and is where I rest the enforcement conclusion. The same appendix table reports minimum detectable effects: at eighty percent power the design can detect wage effects of 3.4 log points, and effects of 2.1 and 1.7 percentage points on formality and self-employment—well below the estimated 4.6 and 3.6—so the compositional findings are not artifacts of an underpowered design straining at noise.

7.5 Sensitivity to violations of parallel trends

Even flat pre-trends are estimated with error, so I apply the sensitivity analysis of Rambachan and Roth (2023). Figure 8 plots the robust confidence set for the average post-reform effect on employment and formality as I allow the post-reform violation of parallel trends to be as large as a multiple $\bar{M}$ of the largest pre-reform violation. The formality and self-employment effects remain bounded away from zero under exact parallel trends but include zero once violations as large as $\bar{M} = 0.1$ are allowed, and the employment effect includes zero even at $\bar{M} = 0$. This is the weakest link in the education-based design, and I flag it plainly: the compositional results are robust to conventional and to design-based inference, but not to

modest violations of parallel trends in the education contrast. Their credibility therefore leans on the two pieces of evidence that do not depend on that contrast—the regional dose-response gradient and the continuous-exposure design with randomization inference. The power calculation of Roth (2022) quantifies why I refuse to lean on passed pre-tests alone: a linear violation of parallel trends that my pre-test would detect only half the time would bias the average post-period formality effect by 0.042—nine tenths of the estimated effect (Appendix Table 11, Panel B). Passed pre-tests are reassuring but not dispositive, which is the posture the paper adopts throughout.

Timing granularity does not drive the estimates either. Monthly event studies (Figure 7), which time wage outcomes by the income reference month and employment outcomes by the interview month, show the formality decline appearing immediately after May 2022 and persisting, with a suggestive dip in the weeks around the decree’s publication on 3 April; and a quarterly event study that bins the right tail at $k \geq 8$, rather than estimating eleven free lags, leaves the estimates unchanged.¹⁰

7.6 Placebo reforms and leave-one-out

I assign fake reforms to each interior quarter of the pre-reform window and re-estimate the DiD using only pre-reform data (Appendix Table 13). The wage placebos are null and the self-employment placebos are marginal in two of three quarters. The employment placebos are large and significant in all three quarters, which is a direct symptom of the pandemic-driven pre-trend in that outcome and the basis for my refusal to interpret the employment estimate causally.

The formality placebos deserve more than a pass-fail reading, because they and the joint pre-trend test answer the same question with different power. All three are negative (-0.024 , -0.029 , -0.017 , the last significant at five percent): although the joint test does not reject ($p = 0.15$), the point pattern indicates a downward relative drift of roughly two percentage points across the pre-window. I therefore quantify what the formality estimate looks like under drift corrections of increasing severity rather than hide behind the passed test. Netting out the placebo-implied drift arithmetically leaves an effect of roughly -0.02 to -0.03 —still more than a tenth of baseline formality, and strikingly close to the synthetic-DiD skill-gap estimate (-0.028), which is immune to group-level drift by construction. Two more aggressive corrections bound the extremes. A specification that allows the two education groups to diverge along a free linear trend over the whole window (Table 4) drives the compositional education-DiD estimates to zero—but this is mechanical, not diagnostic: an

¹⁰The full monthly and binned coefficient series are included in the replication package.

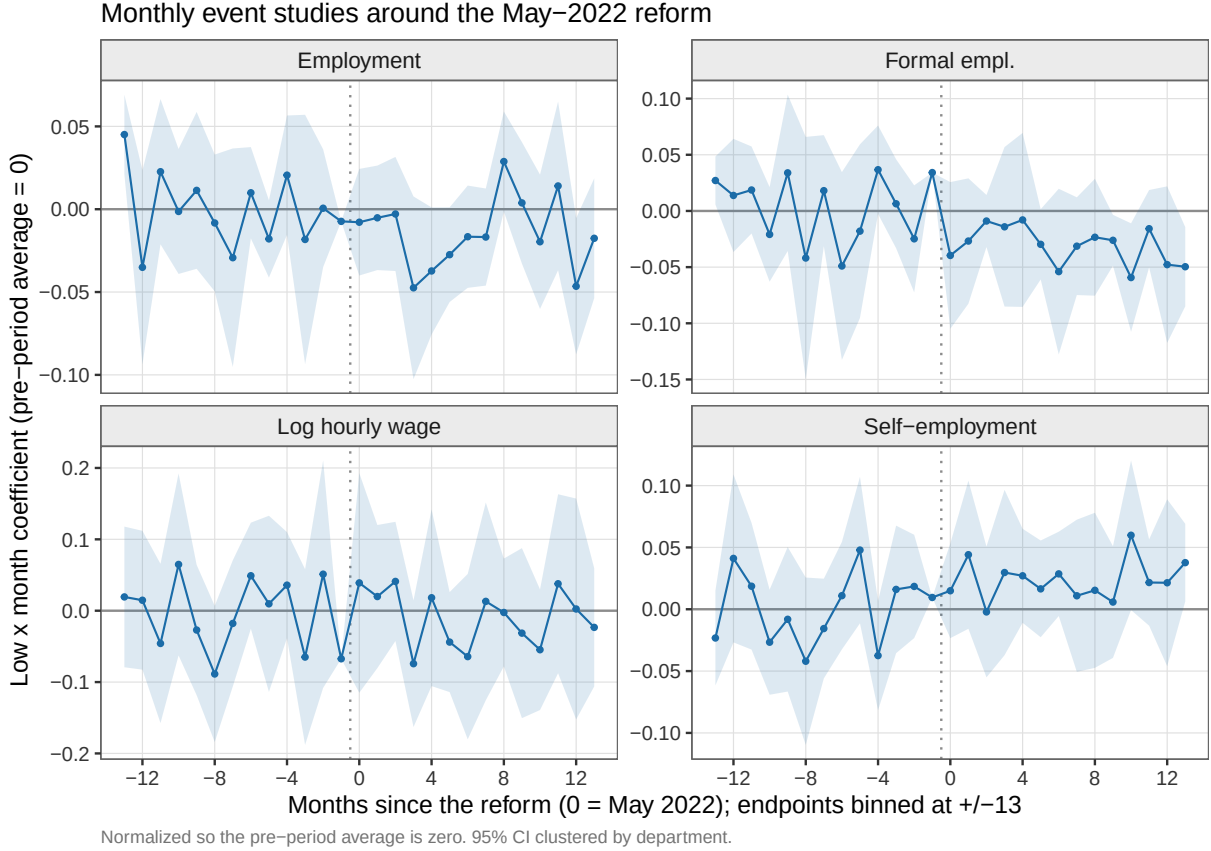

Figure 7: Monthly event studies around the May-2022 reform. Wage outcomes are timed by the income reference month and employment outcomes by the interview month; endpoints binned at ± 13 months; reference month April 2022. Bands: 95 percent confidence intervals clustered by department.

immediate and persistent level shift observed over ten post-reform quarters is itself well approximated by a trend, so this specification absorbs a true step effect along with any drift and is best read as a worst case. Symmetrically, the smoothness restriction of Rambachan and Roth (2023), which extrapolates the fitted linear pre-trend into the post period, yields an uninformative formality interval ($[-0.045, 0.041]$ at $M = 0$): extrapolating four noisy pre-period points across ten post-period quarters explodes the variance. The honest summary is that the education contrast alone cannot separate a persistent level shift from a group trend over a window this long—which is precisely why the causal weight in this paper rests on the regional-exposure design, whose leads are flat, whose inference is design-based, and whose dose-response gradient a group-specific drift cannot generate; and on the convergence of the drift-adjusted education estimate with the synthetic-DiD estimate at -0.02 to -0.03 .

Leave-one-department-out and leave-one-quarter-out re-estimation (Appendix Table 7) leaves the point estimates essentially unchanged for all four outcomes, indicating that no

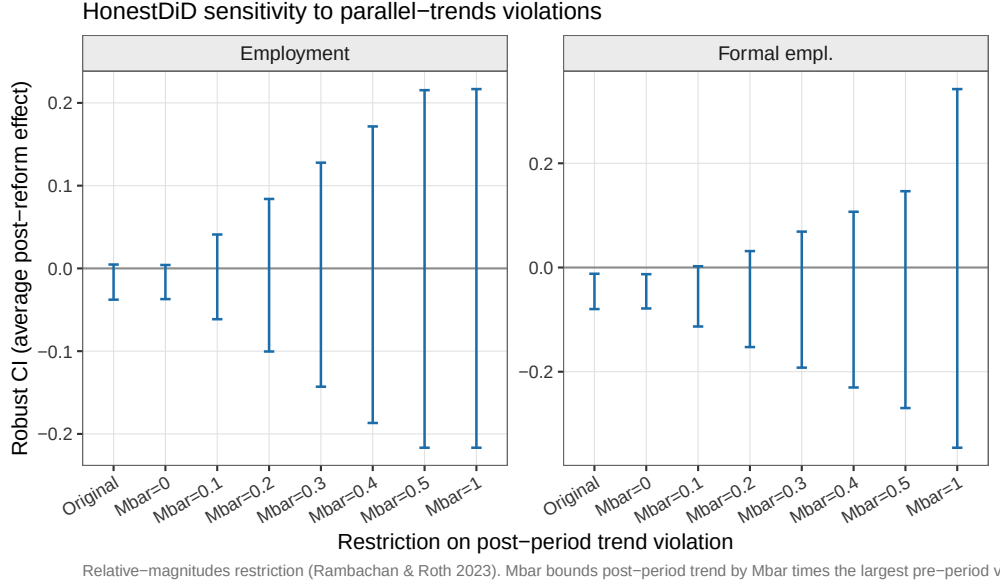

Figure 8: Sensitivity to violations of parallel trends (Rambachan and Roth, 2023). Robust confidence sets for the average post-reform effect under the relative-magnitudes restriction, which bounds the post-reform trend violation by $\bar{M}$ times the largest pre-period v

single region or quarter drives the results.

7.7 A pre-COVID extension of the parallel-trends check

Because my window opens inside the pandemic recovery, I also test the education contrast in normal times, using the annual ENAHO employment modules for 2018–2019 and the quiet window 2018Q3–2019Q4 (after the April-2018 RMV increase and before any further reform). The exercise is doubly informative. On one hand, it counsels humility about the education design in levels: joint tests of the Low $\times$ quarter interactions reject for wages, employment, and self-employment even in this quiet window—low- and high-education outcomes wobble relative to each other at low frequencies in normal times, which is an argument for resting causal weight on the regional-exposure design rather than on the education contrast alone. On the other hand, the *direction* of the normal-times drift runs against my 2022 findings, not toward them: a placebo reform placed at 2019Q1 yields a *negative* self-employment “effect” (−2.2 percentage points) and a positive, insignificant formality one (+0.8 points)—the mirror image of the post-reform pattern. Whatever secular divergence exists between the groups pushed low-education workers toward formality and away from self-employment before the pandemic, so it biases the 2022 reallocation estimates toward zero rather than generating them.

7.8 Out-of-sample validation: the 2025 reform

Finally, I replicate the entire design around the second reform, which raised the minimum wage to 1,130 soles on 1 January 2025, using the 2024 and 2025 quarters. This reform is of almost identical magnitude to the 2022 one but occurs in a calmer, post-pandemic environment. Column (6) of Table 5 reports the estimates. No wage response appears (0.002, standard error 0.011): across two reforms in different macroeconomic conditions, there is no evidence that the minimum wage raised the relative pay of low-skilled workers. The reallocation, however, does not replicate: the formality and employment effects are null around the 2025 reform, and the self-employment effect is small and of the opposite sign. I take this seriously rather than explain it away. It implies that the reallocation I document around 2022 is not a stable structural response that follows every minimum wage increase; it operated in a labor market still re-sorting after the pandemic, in which marginal formal matches were plausibly easiest to dissolve. Section 9 develops this state-dependence interpretation and its alternatives, including the possibility that residual recovery dynamics contribute to the 2022 estimates.

8 Heterogeneity and distributional effects

8.1 Who adjusts?

Figure 9 reports the low- versus high-skilled DiD estimate for each headline outcome within demographic and regional subgroups.¹¹ Three patterns stand out and are consistent with economic intuition about where the minimum wage binds hardest.

First, no subgroup shows wage gains. Whether defined by sex, age, area, or regional bite, every subgroup wage estimate is negative or indistinguishable from zero. The absence of a pay response is a pervasive feature of the data rather than an average that masks offsetting effects.

Second, the compositional adjustment scales with exposure. The decline in formal employment is larger in high-bite departments (−5.5 percentage points) than in low-bite departments (−3.6 points), and the rise in self-employment likewise (+5.0 against +2.8 points). This dose-response pattern is what a causal effect of the wage floor should produce, and it is the cross-sectional counterpart of the continuous-exposure results in Section 7. The employment-level estimate, by contrast, does *not* scale with the bite—it is smaller and in-

¹¹Each estimate is the within-subgroup difference-in-differences, so it asks whether the low- versus high-skilled contrast differs across, say, men and women, not the level effect for a subgroup.

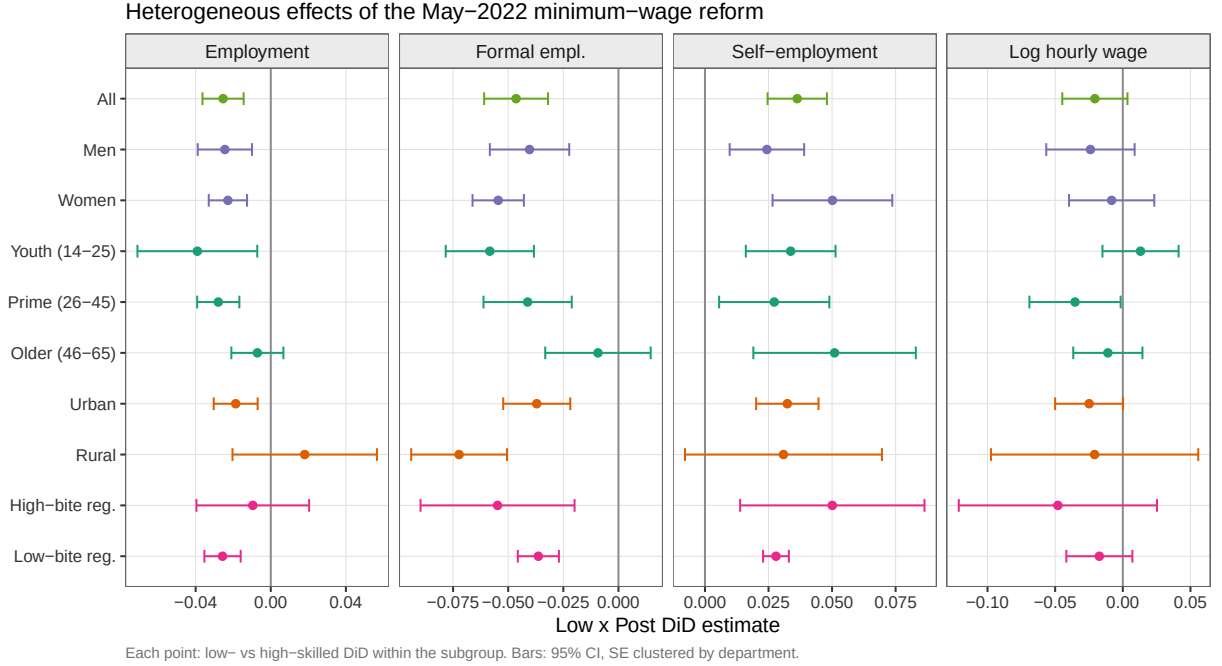

Figure 9: Heterogeneous effects of the 2022 reform. Each point is the Low $\times$ Post DiD estimate within the indicated subgroup, with ninety-five percent confidence intervals based on standard errors clustered by department.

significant in high-bite departments—which is further reason to attribute it to differential recovery rather than to the reform.

Third, the reallocation is concentrated among the young and among women. The decline in formal employment is largest for workers aged fourteen to twenty-five (−5.8 points) and for women (−5.5 points), the groups whose wages are most likely to sit near the floor and whose attachment to formal employment is most tenuous; the rise in self-employment is twice as large for women as for men. For workers over forty-five the formality effect is near zero, though their self-employment also rises. This mirrors the emphasis on youth in the earlier Peruvian literature (Céspedes, 2005; Jaramillo and López, 2006) and the emphasis on women and the least skilled in the developing-country evidence (Katzkowicz et al., 2021; Lemos, 2009).

8.2 Adjustment margins

Where exactly does the reallocation happen? Four mechanism-oriented margins sharpen the picture (Appendix Table 12). First, the share of low-education wage earners employed *without a written contract* rises by 4.5 percentage points relative to high-education wage earners—informalization operates within wage employment, not only through exits into self-

employment. Second, employment recomposes toward *micro units*: the probability that a low-education worker is employed in a establishment of at most twenty workers rises by 2.8 points, and small units are precisely where enforcement is thinnest. Third, using INEI’s decomposition of informal employment (available through 2023), the displaced margin lands in the *informal sector* proper (+2.4 points) rather than in unregistered jobs inside formal firms (+0.8, insignificant): workers did not stay with formal employers under the table; they moved to informal productive units. Fourth, the share of wage earners with under a year of tenure does not move, so the adjustment is not visible as a hiring freeze among those who remain wage earners.

Two further subgroup splits locate the burden. The compositional effects are concentrated almost entirely among *non-heads* of household—secondary earners, whose formality falls 6.8 points against a null for household heads—and among non-indigenous workers, consistent with the urban coastal labor markets where formal employment at the floor is concentrated. The marginal formal jobs that dissolved were, in short, those of secondary earners in small urban firms.

8.3 Distributional wage effects

The absence of an average wage effect could in principle conceal offsetting movements at different points of the wage distribution, since a minimum wage is expected to compress the lower tail. To examine this I estimate unconditional quantile (recentered influence function) regressions in the manner of Firpo et al. (2009), applying the DiD specification to the influence function of each decile of the log real hourly wage. Figure 10 plots the Low $\times$ Post coefficient across deciles. The estimates are non-positive at every decile, mostly between -2 and -4 percent and significant at a few middle deciles; crucially, there is no positive effect at the lower deciles, where a binding and enforced minimum wage would compress the distribution from below. The distributional evidence therefore reinforces the absence of a pay response: the reform did not lift the lower tail of the low-skilled wage distribution relative to the high-skilled. This is consistent with the earnings distribution in Figure 6, which shows little movement toward the new floor, and with the interpretation that in a labor market with widespread non-compliance the statutory minimum did not bind for most low-skilled workers.

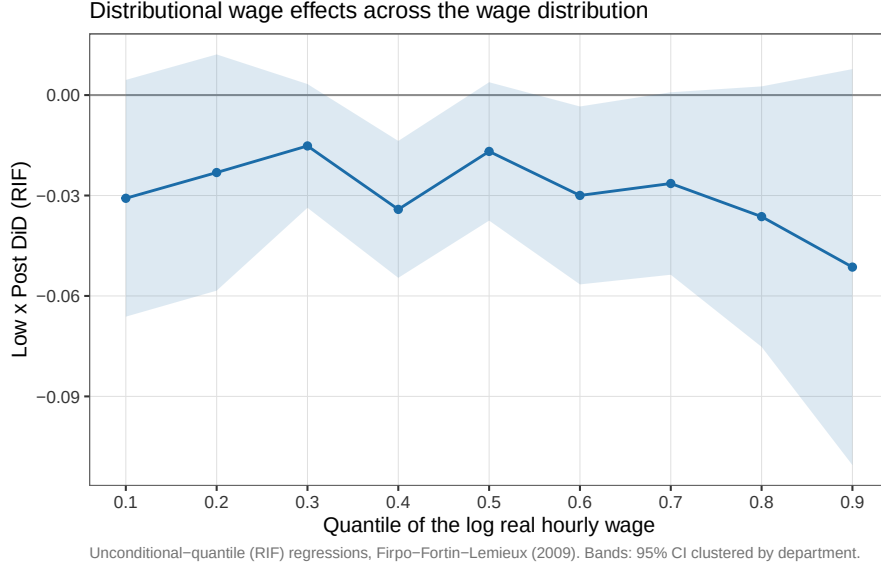

Figure 10: Distributional wage effects. Each point is the $\text{Low} \times \text{Post}$ DiD coefficient from an unconditional-quantile (RIF) regression at the indicated decile of the log real hourly wage (Firpo et al., 2009). Bands are ninety-five percent confidence intervals clustered by department.

9 Discussion

9.1 Mechanisms

The evidence describes a minimum wage that moved workers rather than wages. The re-allocation is my most robust result: formality falls and self-employment rises, the shifts scale with the regional bite of the floor, and they are confirmed by a continuous-exposure design under randomization inference. The natural mechanism is the classic one, a binding floor in the covered sector inducing reallocation to the uncovered sector—the displacement channel that Jaramillo and López (2006) documents for Peru and Ham (2018) for Honduras. Its incidence is exactly where that mechanism predicts: among the young, among women, and in high-bite departments, the workers and places where the new floor cut deepest into the wage distribution. The accompanying rise in hours is consistent with movement toward self-employment, where hours are less constrained.

Why did no aggregate pay response accompany the reallocation? Not because the floor is a dead letter: the first-stage evidence shows that within the formal sector the spike at the old minimum migrated almost completely to the new one, so covered employers complied. The explanation is the arithmetic of coverage in a two-sector labor market (Ulyssea, 2018). Only 13 percent of employed low-skilled workers are formal, so even full compliance inside the formal segment moves the group’s average wage very little; meanwhile pay in the infor-

mal segment drifted *further* below the floor, and the two responses cancel in the aggregate. Inflation compounds this: the 2022 increase of ten percent in nominal terms met consumer price inflation of roughly eight percent, so the real value of the floor barely rose and then eroded. A floor that is honored only where labor costs are enforceable cannot lift the group’s wage distribution, but it can—and on my estimates did—shape which employment arrangements firms and workers choose. This is the same reallocation logic that Dustmann et al. (2022) document across establishments in Germany, transposed to the margin that matters in a developing economy: the boundary between formal and informal work (Jales, 2018).

Two caveats discipline this reading. The reallocation, while robust to specification and to design-based inference, is sensitive to modest violations of parallel trends in the education contrast (Rambachan and Roth, 2023), and it does not reappear around the 2025 reform, where the same design and the same magnitudes yield nulls on every margin and a small opposite-signed self-employment estimate. I interpret the contrast between the two episodes as state dependence: the 2022 increase hit a labor market still re-sorting after the pandemic, in which marginal formal matches—new hires, young workers, small firms—were plentiful and easy to dissolve, whereas the 2025 increase arrived in a settled market with far fewer marginal matches at the floor. I cannot, however, fully exclude the alternative reading, that residual recovery dynamics correlated with education contribute to the 2022 compositional estimates; the dose-response and continuous-exposure evidence is what tilts me toward a causal interpretation, since differential recovery by education has no reason to track the pre-reform regional Kaitz index.

9.2 Reconciliation with the previous literature

My results sit comfortably with some of the prior evidence and in tension with the rest, and the pattern is itself informative. They echo the older Peruvian work of Jaramillo and López (2006), who found the 2003 reform largely innocuous with displacement toward informality, and of Céspedes (2005), who found effects concentrated among the young. They are consistent with the broad international finding that minimum wage increases in this range produce small employment effects (Card and Krueger, 1995; Cengiz et al., 2019).

The tension is with the most recent Peruvian study. Jiménez (2023) finds that the 2016 reform raised formal wages by four to five percent and increased formality, a lighthouse pattern that I do not reproduce for 2022. Three differences plausibly account for the divergence. The 2016 increase occurred in a low-inflation period, so its real bite was larger and more durable than that of the inflation-eroded 2022 increase. The identification differs: Jiménez (2023) uses a department-level dose defined on the formal wage distribution, while I contrast

low- and high-education workers at the individual level, a design that places more weight on the large informal segment of the low-skilled. And the macroeconomic setting differs, stable growth in 2016 against a post-pandemic recovery in 2022. One observation disciplines these explanations: 2016—the lighthouse episode—was itself a calm year, and so was 2025, in which I find no effects at all, so macroeconomic state alone cannot be the whole story. What separates 2016 from 2025 is the *level* of the floor when the increase arrived: in 2016 the minimum stood well below the median wage and a real increase could plausibly propagate as a norm, whereas by 2025 the floor already exceeded the national median, so a further increase started from a level that practice had already ceased to honor for the marginal worker. On this reading the three episodes are ordered by two state variables—how high the floor already sits in the wage distribution, and how much re-sorting the labor market is doing: a moderate floor rising in a stable market can lift norms (2016); a high floor rising amid post-pandemic re-sorting moves the composition margin (2022); and a high floor rising in a settled market moves nothing (2025).

9.3 External validity and limitations

Five limitations bound the interpretation. First, identification rests on the assumption that, absent the reform, low- and high-education workers would have followed parallel paths. I test this where possible and bound the consequences of its failure; the formality pre-trends are flat, but the wage pre-trend test rejects on account of a single early-2021 quarter, and the employment series carries a clear recovery pre-trend, which is why I state the wage conclusion as “no detectable gain” rather than a precise null and treat the employment-level result as inconclusive. Second, the design identifies effects on low-skilled workers relative to high-skilled workers. The comparison group is not entirely unexposed—40 percent of high-skilled wage earners sat below the new floor pre-reform—so the estimates are relative objects that, to first order, understate the effect on the fully exposed; the continuous-exposure design partly addresses this by dispensing with the comparison group. Third, the data are repeated cross-sections, so I cannot follow individuals across the reform or separate worker-level transitions out of formality from changes in the composition of hiring; the compositional results describe net stocks, not gross flows. Fourth, informality in 2024 is measured with a reconstructed indicator rather than the official one; within the 2025 validation window the indicator is reconstructed consistently in every quarter, but the 2024 splice adds measurement error to the tail of the 2022 event study. Finally, the window spans at most ten clean post-reform quarters, so I speak to short- and medium-run effects and not to the long-run adjustment of capital or firm entry and exit.

9.4 Policy implications

The results carry a sober message for minimum wage policy in a high-informality economy. A floor that goes unenforced for most of its intended beneficiaries does little to raise their pay, and where it does bind, in the formal sector, it may nudge some workers toward less protected arrangements. Raising the minimum wage is therefore an imperfect instrument for lifting the earnings of the low-skilled in Peru, a conclusion that echoes Jaramillo and López (2006). This is not to say the minimum wage is harmless or useless; my estimates are relative and my window is short. But it does imply that formalization and enforcement are preconditions for the floor to reach the workers it is designed to protect. Absent them, the margin of adjustment is the composition of employment rather than the level of pay.

10 Conclusion

I have studied how Peru’s 2022 minimum wage increase, from 930 to 1,025 soles, affected workers with different levels of education, using quarterly ENAHO data and a difference-in-differences design that exploits the sharply different exposure of low- and high-education workers to a single national reform. My central finding is that the reform shifted the composition of low-skilled employment rather than the level of low-skilled pay: formal employment fell by 4.6 percentage points—a fifth of its baseline—and self-employment rose by 3.6 points, with flat formality pre-trends, larger shifts where the floor cut deeper into the regional wage distribution, and confirmation from a continuous-exposure design under randomization inference. No pay response accompanied the shift: relative wages of low-education workers did not rise at the mean or anywhere in the distribution, and the share of wage earners paid below the floor did not fall, pointing to non-compliance as the reason the floor could not lift pay. The overall employment effect cannot be pinned down and is confounded by the uneven post-pandemic recovery. Around the identically sized reform of January 2025, in a calmer labor market, neither wages nor composition responded, which suggests that the re-allocation margin operates when the labor market holds many marginal formal matches—as it did during the post-pandemic re-sorting of 2022—and lies dormant when it does not.

The most economical reading of these results is that, in a labor market where informality is pervasive and enforcement is weak, a moderate and inflation-eroded increase in the statutory minimum does not lift the pay of the low-skilled; what it moves, when it moves anything, is the allocation of workers between formal and informal arrangements. This qualifies the lighthouse view of the Peruvian minimum wage that emerges from studies of earlier reforms and points to the informal margin as the central channel of adjustment.

Two directions for future research follow. The first is to exploit panel data—the panel component of ENAHO or the higher-frequency EPEN—to follow individuals across reforms and distinguish worker-level transitions out of formality from changes in the composition of hiring, which my repeated cross-sections cannot separate. The second is to study the interaction between minimum wage policy and enforcement directly, since my results suggest that the returns to raising the floor depend on whether the floor can be made to bind. As additional post-reform quarters accumulate, it will also become possible to trace the longer-run adjustment that a short window such as mine cannot capture.

Declarations

Declarations of interest: none.

Funding: this research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data availability: the ENAHO microdata are publicly available from the Instituto Nacional de Estadística e Informática (INEI). The code that reproduces every table and figure is available in the online replication repository.

A Data appendix

A.1 Sample and variable construction

I pool the twenty quarterly ENAHO employment modules (module 500) for 2021Q1–2025Q4; the main analysis uses 2021Q1–2024Q4 and the validation uses 2024Q1–2025Q4. The working-age sample comprises individuals aged 14 to 65 with non-missing education. All statistics use the module employment weight (`fac500a`). Departments are the 25 first-level administrative units derived from the first two digits of `ubigeo`; the urban indicator is derived from the sampling stratum.

Education and skill groups. Educational attainment is ENAHO variable `p301a`. I verified its coding against the weighted attainment distribution. Low-skilled workers are those with `p301a` in 1–6 (no education through complete secondary); high-skilled workers are those with `p301a` in 7–11 (non-university higher through postgraduate). Special education (code 12) and missing values are excluded.

Labor income and wages. ENAHO records the pay of wage earners per pay period: `p524a1` is the gross payment including overtime and `p523` its frequency (daily, weekly, fortnightly, or monthly). Fifty-four percent of low-education wage earners are paid at non-monthly frequencies, against fifteen percent of high-education wage earners, so I convert all payments to monthly equivalents using the same factors implied by INEI’s own annualized income variable (`i524a1`): 25 for daily, 52/12 for weekly, 2 for fortnightly, and 1 for monthly. Wage earners comprise employees and domestic workers (`p507` in {3, 4, 6}); domestic workers have been entitled to the minimum wage since Law 31047. For employers and own-account workers, labor income is net profit (`p530a`), which is already monthly. Because reported income refers to the month before the interview, I deflate at that reference month (January interviews roll back to December of the previous year) using the Lima consumer price index rebased to December 2021, and I evaluate the statutory minimum in force in the same reference month when classifying workers as paid below the floor. The real hourly wage divides monthly-equivalent labor income by 4.345 times weekly hours in the main occupation (`p513t`, imputed where missing). Wage outcomes exclude public-sector workers, whose pay is set by separate scales, and are winsorized once at the 0.5th and 99.5th percentiles of the pooled private wage-earner sample.

Informality. INEI’s official informal-employment indicator (`ocupinf`, coded 1 for informal and 2 for formal in these files) is present for 2021–2023 but absent for 2024–2025. I reconstruct a consistent indicator from primitives available in every year. A wage employee or domestic worker is classified as formal if affiliated to a pension system (`p558a1`–`p558a4`, whose selected options are marked with their option codes rather than with ones) or holding a formal labor contract (`p511a` in 1–6); an employer or own-account worker is classified as formal if the productive unit is registered (`p510a1`); unpaid family workers are always informal. Validated against `ocupinf` on the overlapping years 2021–2023, this rule agrees with the official classification for 87.8 percent of employed workers and yields an informality rate of 74.9 percent against the official 79.1 percent. I use the official indicator wherever available and the reconstruction only for 2024–2025; within the 2024–2025 validation window the indicator is reconstructed in every quarter, so it is measured consistently there.

Minimum wage and bite. The statutory minimum wage schedule is taken from the decrees and verified against the Banco Central de Reserva del Perú series (PN02124PM); the CPI deflator is BCRP series PN38705PM (Lima, December 2021 = 100), and both inputs are regenerated by a documented script in the replication package. The department Kaitz index is the ratio of the post-reform minimum (1,025 soles) to the department’s pre-reform (2021Q1–2022Q1) weighted median monthly-equivalent wage of private wage earners. The fraction-affected measure is the pre-reform weighted share of private wage earners paid below 1,025 soles.

A.2 Supplementary results

Table 6 reports the triple-difference estimates and Table 7 the leave-one-out stability ranges discussed in Section 7; Tables 8–12 collect the exposure-design diagnostics, the sectoral and occupational checks, the selection bounds and power calculations, the synthetic-DiD and pre-test-power results, and the adjustment margins. Table 13 reports the in-time placebo reforms and confirms that the wage placebos are null while the employment placebos are contaminated by the pandemic pre-trend. The doubly robust estimates of Sant’Anna and Zhao (2020) appear alongside the two-way fixed-effects estimates in Table 2. Figure 11 shows the event study around the January-2025 reform used in the out-of-sample validation.

Table 6: Triple-difference estimates: $\text{Low} \times \text{Post} \times \text{HighBite}$

Outcome	DDD estimate
Log hourly wage	-0.027 (0.038)
Employment	0.015 (0.016)
Formal empl.	-0.018 (0.018)
Self-employment	0.026 (0.018)

Notes: Coefficient on the triple interaction $\text{Low} \times \text{Post} \times \text{HighBite}$, where HighBite indicates departments with an above-median pre-reform fraction of private wage earners paid below the new minimum wage. Department and quarter fixed effects, controls as in the baseline; standard errors clustered by department (25 clusters); ENAHO survey weights. $*p < 0.1$, $**p < 0.05$, $***p < 0.01$.

Table 7: Leave-one-out stability of the baseline DiD estimates

Outcome	Full sample	Drop-one-department range	Drop-one-quarter range
Log hourly wage	-0.021	[-0.027, -0.017]	[-0.026, -0.010]
Employment	-0.025	[-0.028, -0.018]	[-0.031, -0.014]
Formal empl.	-0.046	[-0.050, -0.043]	[-0.052, -0.042]
Self-employment	0.036	[0.032, 0.038]	[0.031, 0.041]

Notes: Ranges of the $\text{Low} \times \text{Post}$ coefficient when re-estimating the baseline dropping one department at a time (25 estimates) or one quarter at a time (15 estimates). Full per-unit estimates are in the replication output (`rob_leaveoneout_detail.csv`).

Table 8: Exposure designs: diagnostics and cell-level estimates

<i>Panel A: regional Kaitz design, exposure-leads joint tests</i>				
Log hourly wage				leads $p = 0.243$
Employment				leads $p = 0.002$
Formal empl.				leads $p = 0.842$
Self-employment				leads $p = 0.202$
<i>Panel B: cell-level fraction-affected designs (transparency exercise)</i>				
Outcome	Exposure	Estimate	(s.e.)	Leads p
Log hourly wage	frac_below	0.129**	(0.056)	0.011
Log hourly wage	frac_aff	0.016	(0.133)	0.004
Employment	frac_below	-0.225***	(0.032)	0.000
Employment	frac_aff	0.391***	(0.072)	0.000
Formal empl.	frac_below	-0.074***	(0.014)	0.007
Formal empl.	frac_aff	0.303***	(0.039)	0.031
Self-employment	frac_below	0.079***	(0.018)	0.244
Self-employment	frac_aff	-0.155**	(0.065)	0.045

Notes: Panel A: joint tests that the pre-reform quarter $\times$ exposure interactions are zero in the regional continuous-exposure design (standardized department Kaitz). Panel B: coefficients on Post $\times$ exposure from cell-level fraction-affected designs (department $\times$ skill $\times$ age cells; frac_below = pre-reform share of the cell's private wage earners paid below 1,025; frac_aff = share paid between 930 and 1,025), with cell and quarter fixed effects and department-clustered standard errors. Both cell-level variants fail their leads diagnostics – fine-grained exposure is confounded with the cells' pandemic-recovery trajectories – which is why the regional design is the preferred corroboration. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 9: Sectoral breadth and occupational dose response of the reallocation

<i>Panel A: education DiD by sector group</i>			
Outcome	Covered high-bite	Agriculture	Other private
Formal empl.	-0.029*** (0.006)	-0.051*** (0.013)	-0.044*** (0.012)
Self-employment	0.028*** (0.007)	0.020 (0.013)	0.030** (0.012)
Log hourly wage	-0.040** (0.018)	-0.060 (0.050)	0.015 (0.014)
<i>Panel B: occupation-exposure dose response (Post $\times$ occupation share below 1,025)</i>			
Outcome	Estimate	(s.e.)	Leads p
Formal empl.	-0.049***	(0.016)	0.008
Self-employment	0.000	(0.017)	0.036
Log hourly wage	0.131***	(0.022)	0.106
Paid below MW	-0.094***	(0.023)	0.000

Notes: Panel A: Low $\times$ Post DiD within sector groups defined from CIIU Rev.4 divisions (covered high-bite: manufacturing 10–33, construction 41–43, trade 45–47, hotels and restaurants 55–56; agriculture: divisions 01–03, under the agrarian regime of Ley 31110, whose daily remuneration is indexed to the RMV and therefore rose with the reform). Panel B: coefficient on Post $\times$ (pre-reform share of the 2-digit occupation’s private wage earners paid below 1,025), with occupation, quarter, and department fixed effects; occupation is measured at the interview and is therefore post-treatment for movers, so Panel B is descriptive corroboration rather than a primary design. Department-clustered standard errors; ENAHO survey weights. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table 10: Selection bounds and statistical power

<i>Panel A: Lee-type trimming bounds, unconditional 2×2 log-wage DiD</i>		
Selection DiD (wage-sample inclusion)	-0.021	
Trimming fraction	0.076	
Untrimmed DiD	-0.005	
Bounds	[-0.099, 0.101]	
<i>Panel B: minimum detectable effects (80% power, 5% size)</i>		
Outcome	Estimate	MDE
Log real hourly wage	-0.021	0.034
Log real monthly earnings	-0.010	0.038
Employed (working age)	-0.025	0.016
Labour force participation	-0.008	0.012
Formal employment	-0.046	0.021
Weekly hours (main job)	0.556	0.698
Full-time (>=35h)	-0.013	0.013
Self-employed	0.036	0.017
Paid below the MW	-0.006	0.021

Notes: Panel A: bounds on the unconditional 2×2 log hourly wage DiD following the trimming logic of Lee (2009): the reform reduced the probability that a low-education worker appears in the wage-earner sample (selection DiD), so the low×post cell is trimmed from above and below by the implied fraction of its baseline rate. Panel B: minimum detectable effect = $2.8 \times$ the department-clustered standard error of the baseline DiD.

Table 11: Synthetic DiD and the power of the pre-trends test

<i>Panel A: synthetic difference-in-differences (high-bite vs synthetic low-bite departments)</i>			
Outcome	Low-education means	Skill gap	
Log hourly wage	0.041 (0.025)	-0.028 (0.048)	
Employment	-0.039*** (0.010)	-0.016 (0.011)	
Formal empl.	-0.013** (0.007)	-0.028 (0.017)	
Self-employment	0.011 (0.011)	0.023 (0.019)	
<i>Panel B: power of the pre-trends test against linear violations (Roth, 2022)</i>			
Outcome	Slope at 50% power	Implied bias (avg. post)	Bias / estimate
Log hourly wage	0.008	0.052	-2.53
Employment	0.006	0.036	-1.43
Formal empl.	0.006	0.041	-0.89
Self-employment	0.006	0.041	1.13

Notes: Panel A: synthetic DiD estimates (Arkhangelsky et al., 2021) on department $\times$ quarter cells, treating above-median-bite departments as treated from 2022Q3; column (1) uses low-education outcome means, column (2) the low-minus-high skill gap; jackknife standard errors in parentheses (the placebo variance is infeasible with 12 treated and 13 control units). Panel B: slope of a linear violation of parallel trends against which the conventional pre-test has only 50 percent power (Roth, 2022), the bias such an undetected violation would induce in the average post-period effect, and its ratio to the estimated effect. $*p < 0.1$, $**p < 0.05$, $***p < 0.01$.

Table 12: Adjustment margins and additional subgroups

<i>Panel A: adjustment margins (Low $\times$ Post)</i>			
Margin	Estimate	(s.e.)	Pre-reform mean
No written contract (wage earners)	0.045***	(0.010)	0.623
Micro firm, ≤ 20 workers (employed)	0.028***	(0.007)	0.854
Tenure < 12 months (wage earners)	-0.012	(0.016)	0.513
Informal job, informal sector (2021-23)	0.024**	(0.010)	0.663
Informal job, FORMAL sector (2021-23)	0.008	(0.007)	0.144
<i>Panel B: subgroups by household role and ethnic self-identification</i>			
Outcome	Group	Estimate	(s.e.)
Employment	Head	-0.003	(0.006)
Employment	Non-head	-0.038***	(0.008)
Employment	Indigenous	-0.004	(0.015)
Employment	Non-indigenous	-0.030***	(0.005)
Formal empl.	Head	-0.005	(0.011)
Formal empl.	Non-head	-0.068***	(0.006)
Formal empl.	Indigenous	-0.030	(0.018)
Formal empl.	Non-indigenous	-0.048***	(0.008)
Self-employment	Head	0.030***	(0.008)
Self-employment	Non-head	0.039***	(0.008)
Self-employment	Indigenous	0.009	(0.017)
Self-employment	Non-indigenous	0.045***	(0.008)
Log hourly wage	Head	-0.020	(0.017)
Log hourly wage	Non-head	-0.019	(0.014)
Log hourly wage	Indigenous	-0.008	(0.029)
Log hourly wage	Non-indigenous	-0.026*	(0.013)

Notes: Panel A: Low $\times$ Post DiD estimates for mechanism-oriented outcomes: the share of private wage earners without a written contract (p511a), the share of private workers in micro units of at most 20 workers (p512a), the share of wage earners with under 12 months of tenure (p513a1/2), and the decomposition of informal employment into informal-sector and formal-sector informal jobs (INEI `emplpsec`, available 2021–2023). Panel B: baseline DiD within subgroups defined by household headship (p203) and indigenous self-identification (p558c). Department-clustered standard errors; ENAHO survey weights. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Deflators. All wage regressions include quarter fixed effects, which absorb national inflation, so log-wage DiD estimates are invariant to the national deflator; and the bite measures compare nominal wages with the nominal statutory floor, so they involve no deflation at all. Department-specific price deflation would matter only for cross-departmental comparisons of real wage *levels*, which play no role in the identification.

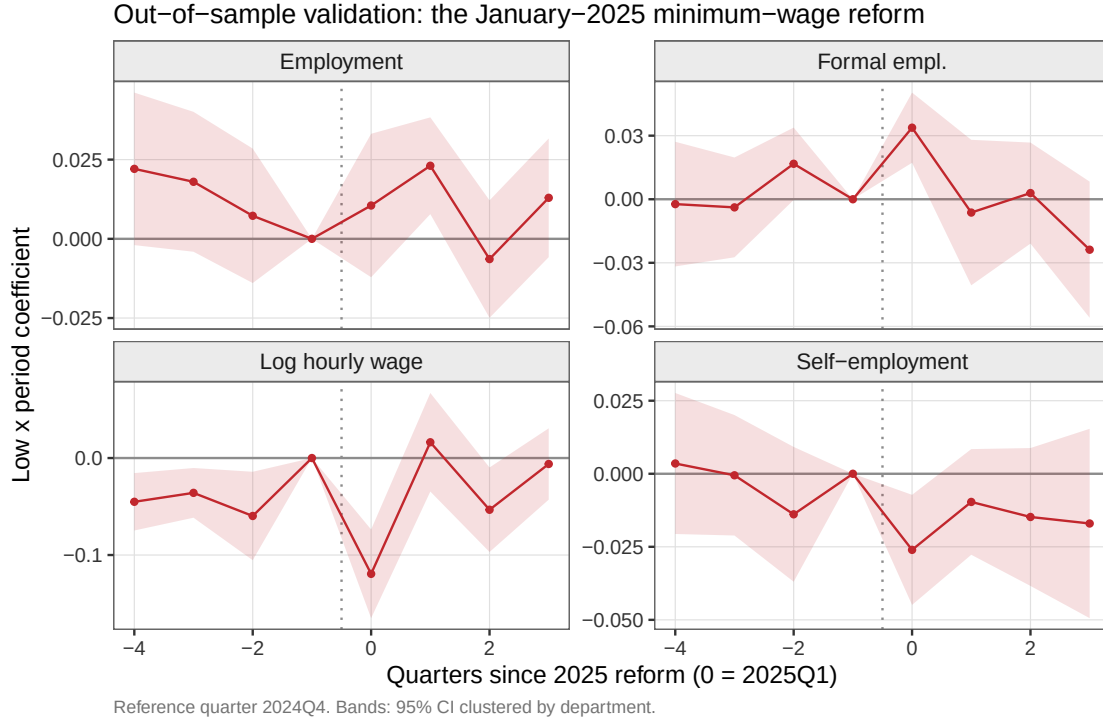

Figure 11: Event study around the January-2025 reform (out-of-sample validation). Coefficients on the interaction of the low-skill indicator with quarter indicators, reference quarter 2024Q4. Bands are ninety-five percent confidence intervals clustered by department.

Table 13: In-time placebo reforms (pre-reform window only)

Outcome	Placebo 2021Q2	Placebo 2021Q3	Placebo 2021Q4
Log real hourly wage	0.010 (0.025)	-0.026* (0.013)	-0.023 (0.015)
Employment	-0.057*** (0.016)	-0.034*** (0.007)	-0.026*** (0.008)
Formal employment	-0.024 (0.015)	-0.029* (0.014)	-0.017** (0.007)
Self-employment	0.027* (0.014)	0.002 (0.009)	0.019* (0.009)

Notes: Each entry is the Low $\times$ Post coefficient from a placebo DiD that assigns a fake reform to the indicated quarter, estimated using only pre-reform data (2021Q1–2022Q1). Standard errors clustered by department in parentheses; all estimates are weighted by ENAHO survey weights. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.
